Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

9 **Abstract**

10 Habitat fragmentation resulting from anthropogenic land-use change may negatively affect
11 both biodiversity and ecosystem structure and function. However, susceptibility to
12 fragmentation varies between species and may be influenced by for instance specialization,
13 functional traits and trophic level. We examined how total and specialist species richness,
14 species composition and functional trait composition at two trophic levels (vascular plants and
15 sap-feeding hoppers) vary with habitat fragmentation (patch size and connectivity) in dry
16 calcareous grasslands in southeast Norway. We found that fragmentation affected plant and
17 hopper species composition both totally and of habitat specialists, but with a net species loss
18 only for the specialists, indicating greater susceptibility of specialized species. Reductions in
19 patch size and increasing isolation negatively affected plant specialists with different sets of
20 traits, effectively reducing the number of species with trait combinations suitable to persist in
21 small *and* isolated patches. Fragmentation influenced trait composition of the total hopper
22 community, but not of habitat specialists. A lesser degree of habitat association could explain
23 why hoppers, despite belonging to a higher trophic level, seemed to be less susceptible to
24 fragmentation than plants. Nonetheless, our study shows that habitat fragmentation affects
25 both species richness, species composition and trait composition of plants and hoppers,
26 indicating that fragmentation leads not only to a loss of species, but also alters dominance
27 hierarchies and the functionality of grassland communities.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

32 **Introduction**

33 Anthropogenic land-use change is currently the most serious threat to global biodiversity (e.g.
34 Haddad et al. 2015) and can result in fragmentation of natural habitats through a combination
35 of habitat loss and patch isolation (Fahrig 2003). These two aspects of habitat fragmentation
36 may together lead to reductions in population sizes and colonization rates, which increase the
37 risk of local species extinctions (Ewers and Didham 2006 and references therein). Such
38 fragmentation-driven reductions in biodiversity may in turn affect ecosystem structure and
39 functioning (Hooper et al. 2005; Isbell et al. 2011).

40 However, not all species are equally susceptible to habitat fragmentation. Rare species
41 and species with a high degree of microhabitat specialization are predicted to be more
42 vulnerable compared to common, generalist species (Ewers and Didham 2006; Henle et al.
43 2004), as specialists are more dependent on the resources in a given habitat type and cannot
44 utilize surrounding areas. A greater sensitivity of specialists has been shown for widely
45 different groups of organisms such as plants (e.g. Adriaens et al. 2006; Dupré and Ehrlén
46 2002; Kolb and Diekmann 2005), fungi (Nordén et al. 2013), arthropods (e.g. Brückmann et
47 al. 2010; Martinson and Fagan 2014; Sang et al. 2010) and birds (Devictor et al. 2008;
48 Matthews et al. 2014). This distinction between generalists and specialists is important, as the
49 negative impacts of habitat fragmentation on specialist species, which are often most
50 important in a conservation perspective, may be masked by generalist species (Jones et al.
51 2015; Matthews et al. 2014; Nickel and Achatziger 2005).

52 Furthermore, how reduced habitat patch size and increased patch isolation affect the
53 species in a community depend on species characteristics such as reproduction potential,
54 dispersal capacity and persistence (e.g. Ewers and Didham 2006; Henle et al. 2004). For
55 instance, species producing few diaspores may be more negatively affected by isolation than

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

56 species with a high reproductive output (Dupré and Ehrlén 2002; Kolb and Diekmann 2005).
57 Further, a high degree of patch connectivity could be more important for species with short
58 dispersal distances compared to long-distance dispersers (Higgins et al. 2003; Jones et al.
59 2015). Finally, traits that positively affect population persistence, such as a long life span,
60 may allow for the formation of remnant populations that persist despite unfavourable
61 environmental conditions and low recruitment rates (Eriksson 1996), making the species less
62 sensitive to habitat fragmentation, at least on short to intermediate time-scales. However, such
63 remnant populations may also be an indication of an unpaid extinction debt (Tilman et al.
64 1994, see also Kuussaari et al. 2009) eventually leading to local extinction.

65 Habitat fragmentation effects have also been suggested to vary between trophic levels
66 (Ewers and Didham 2006). Organisms at higher trophic levels are predicted to be more
67 susceptible to fragmentation as they depend not only on the persistence of a particular habitat,
68 but also their host or prey species, which may in turn show reduced abundance or occurrence
69 when patch size or connectivity is reduced (Schnitzler et al. 2011). Although several recent
70 studies have found greater sensitivity to fragmentation at higher trophic levels (e.g. Cagnolo
71 et al. 2009; Komonen et al. 2000; Kruess and Tschardtke 1994; Roslin et al. 2014), this is not
72 always the case (Schnitzler et al. 2011). Apparently, more knowledge is needed about whether
73 species from different trophic levels living in the same habitat respond similarly to
74 fragmentation. Furthermore, how functional traits determine sensitivity to fragmentation
75 within a landscape for species at different trophic levels is not well investigated (but see
76 Barbaro and van Halder 2009).

77 Although studies of effects of habitat fragmentation have traditionally had a strong
78 focus on species richness or occurrence, rather than species composition (Tschardtke et al.
79 2012), it is increasingly accepted that species composition is a more sensitive indicator of

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

80 ecological change at local scales than species richness (e.g. Vellend et al. 2013, Stork et al.
81 2016). The use of species abundance measures rather than simple presence-absence allows for
82 detection of more fine-scale population declines long before local extinction takes place. For
83 instance, Rösch et al. (2015) found that although species richness did not differ between large
84 and small grassland fragments, some of the rarest species were found only in large habitat
85 patches. Identification of changes in species abundances, and thus species composition, in
86 response to habitat patch size and connectivity, may therefore be of high value for
87 conservation purposes. Relating variation in species composition to functional traits variation
88 along gradients in patch size and connectivity can aid in identifying traits characterizing
89 species that are particularly sensitive to fragmentation (Barbaro and van Halder 2009).

90 Here, we examine how species and functional trait composition at two trophic levels,
91 vascular plants and sap-feeding hoppers (Hemiptera, Auchenorrhyncha), vary with the degree
92 of habitat fragmentation in dry calcareous grasslands in southeast Norway. Dry calcareous
93 grasslands are biodiversity hotspots (Habel et al. 2013), but are declining throughout Europe
94 (LIFE 2008), including Norway (Lindgaard and Henriksen 2011), mainly due to land-use
95 change. Fragmentation of grassland habitats has been shown to decrease species richness and
96 abundance of both plant (Adriaens et al. 2006; Bruun 2000; Evju et al. 2015) and insect
97 species (Brückmann et al. 2010, 2011; Rösch et al. 2013; Öckinger and Smith 2006). Hoppers
98 have low mobility and are thus expected to be more affected by habitat fragmentation than
99 larger, more mobile insect taxa (Rösch et al. 2015). Moreover, whereas little is known about
100 the effect of fragmentation on insect trait distribution in these habitats (although see Öckinger
101 & Smith 2006), sensitivity to fragmentation of grassland plants has been shown to vary
102 among species, with a higher sensitivity particularly for species with a short lifespan or lack
103 of clonal reproduction, traits that are related to low persistence (Bruun 2000; Maurer et al.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

104 2003; Piqueray et al. 2011), and for species with low reproductive potential (Evju et al. 2015;
105 Saar et al. 2012). These findings are, however, based on species occurrence data only.

106 In the current study, we examine both species richness and species composition and
107 functional trait composition of vascular plants and hoppers in habitat patches of varying size
108 and connectivity, aiming to expand our understanding of how sensitivity to fragmentation,
109 and the relationship between habitat specificity, traits and sensitivity, vary across trophic
110 levels. More specifically, we investigate 1) the role of habitat configuration (patch size and
111 connectivity) on plant and hopper species richness and community composition, 2) the
112 importance of species traits for moderating the relationship between species composition and
113 habitat configuration, and 3) whether including all species can mask important patterns of
114 habitat specialists.

115 We predict that 1) species richness of habitat specialists decreases with reduced patch
116 size and connectivity, but that this pattern will be weaker when including generalist species,
117 and 2) that species composition of habitat specialists, but not of the full community, varies
118 along gradients in patch size and connectivity. Moreover, we expect 3) gradients in specialist
119 species composition to be reflected in functional trait composition, with change towards high
120 persistence and high dispersal capacity in small and isolated habitat patches. Finally, we
121 expect 4) patterns to be more pronounced for hoppers than for plants, as hoppers belong to a
122 higher trophic level and have limited dispersal capacity.

123

124 **Materials and methods**

125 *Study area and design*

126 The study was conducted close to the city of Oslo in the inner parts of the Oslo fjord in
127 southeast Norway (see Fig. 1 in Evju et al. 2015) in 2012–2014. Oslo has a mean annual

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

128 temperature and rainfall of 5.7 °C and 763 mm, respectively (Norwegian Meteorological
129 Institute 2015). The study sites were located in dry calcareous grasslands on Cambro-Silurian
130 bedrock on islands or on the mainland. The grasslands occur naturally in a narrow zone
131 between the sea and the forested inlands. They are sun and wind exposed, and the vegetation
132 is dominated by drought-tolerant forbs and graminoids. The habitat is naturally fragmented
133 due to the partial location on islands and the dependency on bedrock qualities, exposure and a
134 warm and dry climate, but habitat loss due to anthropogenic land-use change has led to further
135 fragmentation (Evju and Stange 2016). The grasslands are surrounded by forests and urban
136 and suburban settlements. Yet, these grasslands are biodiversity hotspots for many groups of
137 organisms, including vascular plants and invertebrates, and have a high occurrence of
138 nationally red-listed species confined to this habitat (Henriksen and Hilmo 2015).

139 We mapped fragments of dry calcareous grasslands near Oslo by superimposing a grid
140 system of 500 × 500 m grid cells onto the landscape and randomly selecting 50 grid cells for
141 field survey. Calcareous grassland was found in 22 of these 50 grid cells, totalling 93 habitat
142 patches. We determined patch size for all patches and used a habitat distribution model to
143 estimate patch connectivity as the sum of all neighbour patches within a radius of 1 km of the
144 focal patch, weighted by distance to and size of neighbour patches (Hanski 1994, see Evju et
145 al. 2015 for further details). We used median values of patch size of the 93 patches to define
146 "small" and "large" patches (below and above median size, respectively) and correspondingly
147 median values of patch connectivity to define "high" and "low" connectivity, and categorized
148 all patches as either 1) small with low connectivity, 2) large with low connectivity, 3) small
149 with high connectivity, or 4) large with high connectivity. A subset of 20 habitat patches was
150 sampled in a random, stratified manner, ensuring the inclusion of five patches from each of
151 the four categories, to be included in this study. The size of the 20 habitat patches ranged from

[Type here]

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

152 50 to 2300 m² (mean \pm standard deviation: 762 \pm 584 m²) and patch connectivity from 0.062
153 to 3.92 (1.60 \pm 1.42).

154

155 *Sampling of species and environmental variables*

156 *Plants*

157 In each of the 20 habitat patches, we recorded the occurrence of all vascular plant species
158 (patch-level species richness). Within each patch, plot-level vascular plant species richness
159 and composition was recorded in 0.5 \times 0.5 m sample plots. We randomly placed the sample
160 plots by dividing each patch into grid cells of 1 \times 1 m, numbering them and randomly
161 sampling from the pool of potential plots. The number of plots per patch (n) was weighted
162 with patch area so that $n = 0.15 \times \log_2(\text{patch area})$, rounded off to the nearest integer, to avoid
163 oversampling of small patches. As a result, between 7 and 13 plots per patch were sampled,
164 giving a total of 201 plots over the 20 patches. Each plot was divided into 16 subplots (0.125
165 \times 0.125 m), and the presence of all vascular plant species was recorded in each subplot,
166 giving species abundance as sub-plot frequency. One plot had been mowed and was therefore
167 excluded from the data set, giving a total of 200 plots for analysis. The field work was carried
168 out in August 2012 (18 habitat patches) and August 2013 (2 habitat patches).

169 In each plot we also recorded environmental variables relevant for describing habitat
170 quality for grassland plants: the percentage cover of stone and gravel and of shrubs. A high
171 cover of stone and gravel reflects a shallow soil cover, which should be beneficial for the
172 drought-tolerant calcareous grasslands plants, whereas a high shrub cover implies reduced
173 light availability and thereby reduced habitat quality. From the species abundance data, we
174 calculated the plot-level abundance of invasive species, defined by the Norwegian Black list
175 of species (Gederaas et al. 2012) (see **Table A1.1**), as invasive species are frequently reported

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

176 as a serious threat to dry calcareous grassland biodiversity in the study area (County
177 Administrator of Oslo and Akershus 2010).

178

179 *Hoppers*

180 Due to limited resources, and to ensure sampling in all patches within a short time-period, the
181 hoppers were sampled in a subset of 12 of the 20 habitat patches by randomly selecting three
182 patches from each of the four predefined categories. These 12 patches ranged from 168 to
183 2300 m² (mean \pm SD: 714 \pm 644 m²) with patch connectivity ranging from 0.11 to 3.86 (1.76
184 \pm 1.53), i.e. covering the range of patch size and connectivity in the full dataset. In each patch
185 we recorded hopper species richness and composition by collecting hoppers using a G-vac
186 suction sampler (Stewart and Wright 1995) with a fixed square net of 0.5 \times 0.5 m mounted on
187 the nozzle. We carried out sampling in August 2012, June 2013 and July 2014, with three
188 samples per habitat patch per year, giving a total of nine samples per patch across the study
189 period. One sample consisted of three consecutive 0.25 m² plots, each with a suction time of
190 30 sec. The plot location within the habitat patch was based on randomly selected cells within
191 the 1 \times 1 m grid used for vascular plants as described above, but sample plots for hoppers and
192 vascular plants were not identical.

193 The identification to species level of female specimens of several leafhopper genera
194 (*Alebra*, *Anaceratagallia*, *Arboridia*, *Balclutha*, *Chlorita*, *Cicadula*, *Elymana*, *Empoasca*,
195 *Euscelis*, *Jassargus*, *Javesella*, *Kelisia*, *Rhopalopyx*, *Ribautodelphax*, *Streptanus*) was not
196 possible (Biedermann and Niedringhaus 2004). Females were therefore allocated to species
197 based on proportion of males in the same sample (251 individuals, 10% of the total sample).
198 If only one species of a genus was represented in the dataset, all female specimens were
199 allocated to that species. If male specimens were not present, females were only identified to

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

200 genus level (389 individuals, 16%) (see Rösch et al. 2015). Fragmented specimens or
201 specimens that could not be identified to genus level were excluded from the analysis (83
202 specimens in total, 3.5 % of the total sample).

203 Denno & Roderick (1991) emphasize the role of the vegetation in structuring hopper
204 communities. We therefore recorded several environmental variables relevant for describing
205 habitat quality for the hoppers: patch-level plant species richness, both totally and of habitat
206 specialists, and shrub cover. In addition, plant species composition, derived as mean patch
207 ordination scores from the analyses of the plant species-plot matrices of all plants and habitat
208 specialists (see *Statistical analyses*) was used.

209

210 *Species traits*

211 A list of habitat specialists of vascular plants (Evju et al. 2015) was used to characterize the
212 plant species as either habitat generalists or specialists (**Table A1.1**), that is, species which are
213 strongly confined to dry calcareous grasslands within the study area. For all plant species,
214 information on functional traits important for reproductive potential, dispersal and persistence
215 (**Table 1a**) were collected from trait databases (Fitter and Peat 1994; Kleyer et al. 2008; Kühn
216 et al. 2004) and the local flora (Lid and Lid 2005). Median trait values were used when
217 several records were available in the databases. To characterize reproductive potential, we
218 used the number of seeds produced per ramet. Dispersal capacity was represented by seed
219 mass and dispersal agent (wind, animal or unassisted, cf. Jones et al. 2015). Plant persistence
220 was represented by lifespan, clonality and three traits characterizing competitive ability.
221 Species were classified as short-lived (annual or biennial) or long-lived, being either non-
222 clonal, clonal with shortly creeping clonal offspring, or clonal with far-creeping clonal
223 offspring (cf. Fitter and Peat 1994). Finally, canopy height, specific leaf area (SLA) and leaf

[Type here]

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

224 size were selected to represent competitive ability, with tall, fast-growing (high SLA) plants
225 with large leaves predicted to have a higher competitive ability (Weiher et al. 1999) and thus
226 higher persistence.

227 The hopper species were also classified into habitat generalists and specialists (**Table**
228 **A1.2**). We used two criteria for the classification: habitat preference and expert opinion (H.
229 Nickel, A. Endrestøl). Some species that are not considered specialists on calcareous
230 grasslands elsewhere in Europe are in Norway restricted to the calcareous grasslands in the
231 inner Oslo fjord due to favourable climate and the associated vegetation communities found
232 here. Functional traits of hoppers were aggregated mainly from Biedermann and Niedringhaus
233 (2004), Nickel (2003), Ossiannilsson (1978, 1981, 1983) and Söderman (2007) (**Table 1b**).
234 Reproductive potential was represented by the number of generations per year. As short-
235 winged (brachypterous) morphs of dimorphic hopper species have low dispersal capacity, but
236 higher fecundity than long-winged morphs (Denno and Roderick 1991), we used the
237 proportion of brachypterous individuals sampled to represent both dispersal capacity and
238 reproductive potential. The proportion of brachypterous individuals could be expected to vary
239 among patches according to available resources and population density (della Giustina 2002;
240 Denno and Roderick 1991), but in our dataset the abundance of most species was too low to
241 calculate patch-specific proportions. Thus, the data were pooled over all patches. Dispersal
242 capacity was also represented by body length, as larger species may be better dispersers
243 (Denno and Roderick 1991). We used the mean body size across both sexes for species with
244 sexually dimorphic body size. Overwintering style is a trait that should be related to
245 population persistence, as more exposed overwintering modes result in higher winter
246 mortality (Denno and Roderick 1991). Overwintering style (egg, nymph or adult) was
247 therefore used as a proxy for population persistence. Finally, diet width has been hypothesized

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

248 to influence population persistence as polyphagous species utilizing a range of host plants
249 may have a higher probability of survival (MacLean 1983) in a fragmented landscape. Thus,
250 we included diet width (monophagy, oligophagy, polyphagy) as a persistence trait.

251

252 *Statistical analyses*

253 To examine whether measures of habitat quality varied systematically along gradients in
254 patch size or connectivity, we used linear mixed-effect models with the habitat quality
255 variable as response and either patch size or connectivity as predictor. Plots nested in patch
256 were used as random factors to account for the spatial autocorrelation of sample plots. For
257 plants, cover of stone and gravel, cover of shrubs and abundance of invasive species were
258 used as response variables. For hoppers the relevant environmental variables showed a large
259 degree of collinearity. We calculated variance inflation factors (VIFs) (Zuur et al. 2007) and
260 used these to simplify our set of environmental variables. We retained cover of shrubs, total
261 plant species richness, habitat specialist plant species richness, and mean patch score along
262 GNMDS axis 2 of the total plant species composition.

263 Further, we used generalized mixed-effect models to examine whether species
264 richness of plants and hoppers at the sample-plot level varied between patches according to
265 patch size and connectivity. Because of low species richness and abundance of hoppers, we
266 pooled data across samples for each year, giving three replicates for each habitat patch. We
267 analysed total species richness and richness of habitat specialists separately, and plots nested
268 in patch were used as random factors. Predictor variables were patch size, patch connectivity
269 and their interaction. Likelihood ratio tests were used for model simplification and to assess
270 variable significances. Models were run with poisson-distributed error terms.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

271 We used multivariate ordination techniques (global non-metric multidimensional
272 scaling; GNMDS) to derive the first and second ordination axis of community composition
273 for both plants and hoppers. Separate ordinations were run for total species composition and
274 species composition of habitat specialists. The two-dimensional GNMDSs were run with
275 Bray-Curtis dissimilarity measure, 100 initial configurations, maximum 200 iterations and
276 stress tolerance 10^{-7} and axes were scaled in half-change units. We calculated the correlation
277 coefficient between GNMDS ordination axis scores and environmental variables using the
278 non-parametric Kendall's τ .

279 To directly test the importance of patch size and connectivity for species composition,
280 we used the constrained ordination technique canonical correspondence analysis (CCA). We
281 applied a step-wise procedure where we first separately tested the importance of patch size,
282 and of patch connectivity. The variable that alone explained most of the variation in species
283 composition was then used as a conditioning variable. By using the other variable as a
284 constraining variable, we tested whether it contributed to explaining additional variation in
285 species composition. Finally, we tested the significance of the interaction between patch size
286 and connectivity by using both patch size and connectivity as conditioning variables. We used
287 Monte Carlo permutation tests with 999 permutations to test whether the explanatory
288 variables explained more variation in the species composition than a random variable.

289 To examine how trait composition of the habitat specialists varied along gradients of
290 patch size and connectivity, we calculated community-weighted mean traits per sample plot as
291 the mean plot trait value weighted by the abundance of the species in the plot. Community-
292 weighted means thus reflect the traits of the most abundant species in the community. Due to
293 the widely different scales of the traits, the community weighted mean traits were centred and
294 scaled before applying a constrained ordination technique, redundancy analysis (RDA), to test

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

295 the importance of patch size and connectivity for explaining variation in community trait
296 composition. The test procedure followed the description given for the CCA.

297 All analyses were performed in R version 3.2.2 (R Core Team 2015) using RStudio
298 version 099.489 (RStudio, Inc., Boston, Massachusetts, USA). We used the packages *vegan*
299 (Oksanen et al. 2015) and *MASS* (Venables and Ripley 2002) for the multivariate analyses,
300 and *lme4* (Bates et al. 2015) for the mixed-effects models.

301

302 **Results**

303 *Environmental variables*

304 For the 20 habitat patches sampled for plants there was a tendency for larger patches to have a
305 higher plot-level cover of shrubs ($\beta = 0.238$, $SE = 0.116$, $p = 0.055$), while invasive species
306 were more abundant in small patches ($\beta = -0.515$, $SE = 0.134$, $p = 0.001$) and isolated patches
307 ($\beta = -0.280$, $SE = 0.131$, $p = 0.047$).

308 For the subset of 12 habitat patches sampled for hoppers patch-level shrub cover
309 increased with patch size ($\beta = 0.248$, $SE = 0.049$, $p < 0.001$). In addition, patch-level plant
310 species richness increased slightly with patch size ($\beta = 0.141$, $SE = 0.057$, $p = 0.033$), whereas
311 the number of habitat specialist plants increased with both patch size ($\beta = 0.376$, $SE = 0.066$,
312 $p < 0.001$) and patch connectivity ($\beta = 0.137$, $SE = 0.058$, $p = 0.040$).

313

314 *Plant species richness*

315 We recorded 158 taxa of vascular plants, between 27 and 59 species per patch. A total of 27
316 species (17%) were classified as habitat specialists (**Table A1.1**). The mean number of plant
317 species per plot was 13.7 (range: 4–29), of which habitat specialists on average constituted
318 33% (mean: 4.5, range: 0–12). The plot-level species richness was not related to patch size or

[Type here]

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

319 connectivity (**Table 2a**). In contrast, the plot-level habitat specialist species richness increased
320 with increasing patch size, and with a significant patch size \times connectivity interaction,
321 suggesting that the positive effect of patch size increased with increasing connectivity.

322

323 *Plant species composition*

324 Species turnover of plants between plots was low, as indicated by relatively short ordination
325 axes (**Fig. 1, Fig. A2.1**). The longest axis was about 1 half-change unit, corresponding to a
326 50% species turnover. Species composition, both totally and of habitat specialists only, varied
327 along gradients in soil depth (cover of stone and gravel), cover of shrubs and cover of
328 invasive species (**Fig. 1, Fig. A2.1, Table A2.1**). Additionally, both patch size and patch
329 connectivity correlated with the ordination axes. Thus, although other environmental variables
330 were important in structuring species composition, there seemed to be a shift in species
331 composition also from small to large and isolated to well-connected patches.

332 The constrained ordinations showed that patch size and connectivity were significant
333 predictors of variation in species composition of both the total plant community and of the
334 habitat specialists (**Table 3a, Table A2.2a**). For the specialists, patch connectivity alone
335 explained 3.7% of the variation in the species-plot-matrix. Both patch size and the interaction
336 between connectivity and size contributed to explaining additional variation, with all variables
337 combined explaining 6.2% of the variation. Similarly, all variables combined explained 5.0%
338 of the variation in total species composition.

339

340 *Plant trait composition*

341 Patch connectivity, patch size and their interaction in combination explained significantly
342 more of the variation in plant trait composition than expected at random (total plant

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

343 community: 8.2%, habitat specialists: 5.7%; **Table 3b, Table A2.2b**). For the specialists,
344 plots in isolated patches were dominated by non-clonal species with many wind-dispersed
345 seeds, whereas short-lived species and species with few seeds without any specific dispersal
346 mechanism were more abundant in well-connected patches (**Fig. 2**). The abundance of tall,
347 long-lived species with large, thin leaves (high SLA) and large seeds increased with
348 increasing patch size (**Fig. 2**). The pattern was somewhat different for trait composition of the
349 total plant community: Short-lived species were more abundant in isolated patches, whereas
350 long-lived species dominated in well-connected patches (**Fig. A2.2**). Species with wind-
351 dispersed seeds were more common in large patches, while species without a specific
352 dispersal mechanism were typical of small patches. For both the total plant community and
353 the habitat specialists the interaction between patch size and connectivity had the same
354 direction as the main effect of patch connectivity, suggesting that a large patch size enhanced
355 the effect of connectivity.

356

357 *Hopper species richness*

358 For hoppers, 2397 individuals were determined to 74 taxa, of which 68 (2364 specimens)
359 were determined to species level and 6 (33 specimens) to genus level (**Table A1.2**), with
360 species richness ranging from 14 to 30 per patch. In total, 13 species (18%) were classified as
361 habitat specialists. Plot-level species richness was 11.8 (range 4–22), including on average 3.2
362 (27%) habitat specialists (range: 0–6). Plot-level species richness of hoppers was not related
363 to patch size or connectivity (**Table 2b**). Specialist hopper richness was, however, positively
364 related to patch connectivity.

365

366 *Hopper species composition*

[Type here]

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

367 Species turnover between plots was slightly higher for hoppers than for plants, as indicated by
368 the somewhat longer ordination axes (**Fig. 3, Fig. A2.3**). Total species composition of
369 hoppers varied with plant species composition and plant specialist species richness (**Fig. 3,**
370 **Table A2.3**). Additionally, both patch size and patch connectivity correlated with the
371 ordination axes. Specialist species composition shifted along gradients in plant species
372 richness and composition, but not patch size or connectivity (**Fig. A2.3, Table A2.3**).

373 As both richness, composition and structure of plant communities were partly
374 influenced by habitat configuration, however, we wanted to directly test the effects of patch
375 size and connectivity also on hopper species composition. Patch connectivity alone explained
376 5.8 and 8.5% of the variation in the species-plot-matrix for the total hopper community and
377 habitat specialists, respectively (**Table 3c, Table A2.4a**). Patch size did not contribute to
378 explaining additional variation in the matrix.

379 ***Hopper trait composition***

381 The constrained ordination showed that patch size explained 8.4% of the variation in trait
382 composition for the total hopper community (**Table A2.4b**), significantly more than expected
383 at random. Plots in large patches were dominated by species which overwinter as adults and
384 have several generations per year, whereas plots in small patches were dominated by species
385 with lower reproductive potential (**Fig. A2.4**). There was no additional variation in trait
386 composition related to patch connectivity. Trait composition of the specialist hopper
387 community was not influenced by habitat configuration (**Table 3d**).

388

389 **Discussion**

[Type here]

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

390 Most aspects of the calcareous grassland plant and hopper communities in the study
391 area were affected by habitat fragmentation. This is in line with previous studies showing that
392 increasing isolation and decreasing patch size influence plants and invertebrates in grasslands
393 throughout Europe (e.g. Brückmann et al. 2010; Krauss et al. 2010; Rösch et al. 2015).
394 Whereas most fragmentation studies focus on one community property, mainly species
395 richness, our study shows that fragmentation also affects species composition and trait
396 composition, implying that habitat fragmentation leads not only to local species extinctions,
397 but also alters species dominance hierarchies and the functionality of these communities.

398

399 *Species richness and composition*

400 As hypothesized, we found lower plot-level species richness of both specialist plants
401 and hoppers when habitat patches were increasingly isolated, of plants also when patch size
402 decreased. Several studies show that connectivity is important for species richness of various
403 insect taxa in fragmented landscapes (Kormann et al. 2015; Öckinger et al. 2010; Öckinger
404 and Smith 2006), and our study suggests that habitat configuration is indeed important for
405 hoppers confined to dry and warm grasslands (see also Biedermann 2002 and references
406 therein; Rösch et al. 2013; 2015). The richness of grassland plants has been shown to vary
407 with both patch size and landscape connectivity (e.g. Adriaens et al. 2006; Bruun 2000;
408 Brückmann et al. 2010), also in our study area, where we have previously demonstrated a
409 higher patch-level specialist species richness in larger and more well-connected patches (Evju
410 et al. 2015, Evju & Sverdrup-Thygeson 2016). The higher plot-level species richness suggests
411 that this pattern is not only due to higher microhabitat diversity in large fragments, but also to
412 colonization-extinction dynamics (Giladi et al. 2014; Rosenzweig 1995).

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

413 In contrast to our findings for the habitat specialists, total species richness of plant and
414 hoppers were not affected by habitat fragmentation. This higher sensitivity of habitat
415 specialists confirms previous results from the same study area (Evju et al. 2015) and other
416 studies from calcareous grasslands (e.g. Adriaens et al. 2006), as well as other grassland
417 habitats (Henderson 2010). Together, our findings emphasize the need to focus on habitat
418 specialists when assessing the negative impacts of habitat fragmentation on species richness,
419 as reduced connectivity and patch size may not affect richness of species with broad habitat
420 requirements, which can persist also in matrix habitats (Jones et al. 2015; Matthews et al.
421 2014).

422 Whereas fragmentation effects on plant and hopper specialist were obscured by
423 including generalists when examining species richness, this was not the case when
424 considering species composition. Contrary to our expectation, both plant and hopper
425 generalist and specialist species composition were affected by habitat fragmentation.
426 Similarly, Rösch et al. (2015) found that species composition of plant and invertebrate
427 specialists and generalists varied with patch size. By simultaneously examining effects of
428 fragmentation on species richness and community composition, we show that species
429 abundances and/or species identity of both the total and the specialist plant and hopper
430 communities are influenced by fragmentation, but with a net species loss only for the
431 specialists.

432

433 *Functional traits*

434 The shift in species composition was accompanied by a corresponding shift in the
435 composition of functional traits of the total and specialist plant community, as well as the total
436 hopper community, indicating that the abundant species in the community are functionally

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

437 different in small and isolated compared to large and well-connected patches. Further, our
438 results suggest that different suites of traits determined species sensitivities to different
439 aspects of fragmentation. For plant specialists, reproduction and dispersal-related traits were
440 more strongly affected by isolation, as suggested by Lindborg et al. (2012), implying that as
441 the distance between remaining fragments increases, the abundance of specialist plants with a
442 relatively short life-cycle and low reproduction and dispersal capacity declines (Evju et al.
443 2015; Jones et al. 2015). On the other hand, there was a tendency for traits associated with
444 population persistence, such as a long life span, to be positively related to patch size. This
445 may seem counterintuitive, as long-lived species could be expected to persist as remnant
446 populations (sensu Eriksson 1996) despite suboptimal habitat conditions in small habitat
447 patches (see Maurer et al. 2003; Piqueray et al. 2011). However, our findings are in
448 accordance with Lindborg et al. (2012), who suggest that persistent species may be more
449 sensitive to habitat loss because of their limited capacity for re-colonization once locally
450 extinct. Although reductions in patch size and increasing isolation occur simultaneously as a
451 habitat is fragmented, our results emphasize that the two processes favour species with
452 different sets of traits, effectively reducing the number of species with a trait combination
453 suitable to persist in small *and* isolated patches.

454 Contrary to the plants, the shift in hopper specialist species composition was not
455 accompanied by a corresponding shift in trait composition. This was unexpected, as trait
456 composition of the total hopper community was influenced by patch size (although not
457 connectivity), with higher abundance of traits corresponding to low reproductive output in
458 small patches. Several factors may contribute to this lack of pattern for the specialists. First,
459 the definition of habitat specialists may be less straightforward for hoppers than for plants.
460 Hoppers depend on their host plants, but few of the species in our study were monophagous

[Type here]

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

461 on plants restricted to dry calcareous grasslands. Rather, they were confined to dry and warm
462 habitats, which could also prevail outside the defined patches. Second, our definition of
463 specialists included only 13 species, many of which have low abundances, which limits the
464 statistical power. However, the proportion of specialist species was almost identical for
465 hoppers (18%) and plants (17%), indicating no disproportional undersampling of hopper
466 specialists. Third, we have less knowledge of the link between traits and function for
467 invertebrates, including hoppers, than for plants. Thus, we cannot be certain that the traits we
468 have included are relevant descriptors of the variation in function we hypothesize is important
469 for the fragmentation response. Fourth, the traits are compiled mainly from central European
470 literature and may be less relevant for our study system (e.g. Söderman 2007, Endrestøl
471 2014). Finally, a relatively small sample size (in terms of patches) may have restricted our
472 possibilities to find significant patterns.

473 Nonetheless, across organism groups the effect of habitat fragmentation on trait
474 composition varied depending on whether all species or only habitat specialists were included
475 in the analyses. For specialist plants reproduction and dispersal-related traits were affected by
476 isolation, whereas persistence traits were mainly associated with patch size. For the total plant
477 community, the pattern was opposite, with persistence traits related to isolation and dispersal
478 traits to patch size. Together with our findings for the hoppers, where trait composition of the
479 total community, but not specialists, were affected by fragmentation, this indicates again that
480 including generalist species in the analyses may obscure fragmentation effects on habitat
481 specialists, which are the main targets for conservation.

482

483 *Trophic levels*

[Type here]

Olsen, Siri Lie; Evju, Marianne; Endrestøl, Anders.

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

484 Whereas several other studies show greater sensitivity to fragmentation at higher
485 trophic levels (e.g. Roslin et al. 2014 for a study including both plants and insects), this did
486 not seem to be the case in our study. Specialist hoppers seemed to be less vulnerable to habitat
487 fragmentation than specialist plants. For instance, the main axes of plant habitat specialist
488 composition were related to both patch size and connectivity in the unconstrained ordination.
489 For the specialist hoppers, variables derived from the plant community data explained most of
490 the variation in species composition, with no additional contribution from patch size or
491 connectivity, suggesting that fragmentation influences hopper specialists primarily through
492 the plant species they feed on (Schaffers et al. 2008). As discussed above, none of the
493 specialist hoppers were monophagous on specialist plants species, indicating that the
494 composition of the hopper community was mainly determined by other plant community
495 properties than the occurrence of specialist plants. For instance, total plant species richness,
496 which was not affected by habitat fragmentation in our study, can be an important predictor of
497 hopper species richness (Rösch et al. 2013), as species rich and structurally diverse plant
498 communities provide a larger heterogeneity of resources for the herbivores (Nickel and
499 Hildebrandt 2003; Scherber et al. 2010). Thus, the degree of specialization seems more
500 important for sensitivity to fragmentation than trophic level *per se*.

501

502 ***Environmental variables and invasive species***

503 Local environmental variables can be more important in explaining species occurrences than
504 habitat configuration (Adriaens et al. 2006; Dupré and Ehrlén 2002), and if habitat loss leads
505 to subsequent degradation of remaining habitat, the effects of fragmentation can be
506 reinforced. Whereas hopper species composition was mainly determined by properties of the
507 plant community, plant species composition was, in addition to patch size and connectivity,

Fragmentation in calcareous grasslands: species specialization matters. *Biodiversity and Conservation* 2018

DOI [10.1007/s10531-018-1540-z](https://doi.org/10.1007/s10531-018-1540-z)

508 structured mainly by variation in soil depth, cover of shrubs (i.e. light availability) and the
509 cover of invasive species. Invasive species were more abundant in small and isolated patches
510 in our study area, which could partly explain the shift in total plant species and trait
511 composition with habitat fragmentation. Some invasive species, such as *Phedimus spurius*,
512 form dense mats and may displace native species, thereby contributing to the lower species
513 richness of habitat specialists (M. Evju, unpublished results) in small and isolated patches.
514 Restoring habitat quality is therefore important to reduce the negative effects of habitat
515 fragmentation on biodiversity.

516 It is hard to disentangle the effects of systematic differences in environmental
517 variables between patches (e.g. shrub cover and the cover of invasives) and the effects of
518 habitat fragmentation *per se*. However, the higher cover of invasive species in small and
519 isolated patches in our study system is most likely a direct effect of habitat fragmentation, as
520 invasive species colonize fragmented habitats more easily (Vilà and Ibáñez 2011). Thus,
521 changes in environmental variables and thereby habitat quality is one of the many aspects of
522 habitat fragmentation and needs to be taken into account in management of fragmented
523 landscapes.

524

525 **Conclusions**

526 Species richness of specialist hoppers increased with connectivity. Large, well-connected
527 patches also contained more specialist plants both at the patch level (Evju et al. 2015) and the
528 plot level (this manuscript). Conservation of large, well-connected patches thus ensures the
529 diversity of habitat specialist of both plants and hoppers. Reduced patch size had the greatest
530 negative effect on plant specialists with traits enhancing population persistence, whereas
531 increased isolation negatively affected short-lived species and species with limited

532 recruitment and dispersal capacity. Conservation of large, well-connected patches will
533 therefore also sustain larger populations of habitat specialists that exhibit traits which make
534 them especially vulnerable to fragmentation. Finally, our study shows that ensuring habitat
535 quality in remaining patches is an important aspect of habitat conservation.

536

537 **Acknowledgements**

538 This study was carried out under the projects “Survey and monitoring of red-listed species”
539 (ARKO, funded by the Norwegian Environment Agency), and “Management of biodiversity
540 and ecosystem services in spatially structured landscapes” (funded by the Norwegian
541 Research Council, grant 208434/F40). We are grateful to A. Often, O. Skarpaas, O.E.
542 Stabbetorp and J. Wesenberg for field work contributions and H. Nickel for inputs on hopper
543 generalist and specialist classification, and to two anonymous reviewers for valuable inputs on
544 a previous version of the manuscript.

734 **TABLES**

735 **Table 1.** Overview of the traits used in the analyses for a) vascular plants and b) hoppers. The traits represent reproductive potential, dispersal
 736 capacity and persistence and are hypothesized to predispose species for vulnerability to fragmentation. For each trait is given: a description of the
 737 trait, scale, min, max and mean values (continuous traits) or percentage of species with given trait category (ordinal traits) for habitat specialists
 738 and generalist species, as well as the data source. Modified from Evju et al. (2015) and extended with hopper data.

739 a)

Characteristic	Predisposing for sensitivity to fragmentation	Trait	Description	Scale	Specialists	Generalists	Source
Habitat requirements							
Habitat requirements	Narrow habitat requirements	Habitat specialist	Species confined to dry calcareous in the study area (1), generalist species (0)	binomial	n = 27	n = 131	Evju et al. 2015
Reproduction							
Reproductive potential	Low reproductive potential	Seed number	No. of seeds per ramet/plant	continuous	Min: 17.0 Max: 13 202.2 Mean: 1 448.7	Min: 5.7 Max: 400 104.8 Mean: 11 539.3	Kleyer et al. 2008
Dispersal							
Dispersal capacity	Low dispersal capacity	Dispersal agent	1. wind-dispersed 2. animal-dispersed 3. no dispersal aid	ordinal	1: 11.1 % 2: 18.5 % 3: 70.4 %	1: 13.7 % 2: 9.9 % 3: 76.3 %	Lid and Lid 2005, Fitter and Peat 1994

 757 species-plot matrix of habitat specialist hoppers, d) RDA of trait-plot matrix of habitat
 758 specialist hoppers. The model best explaining the variation in the matrix is shown in bold. · p
 759 < 0.1, * p < 0.05, ** p < 0.01, *** p < 0.001

760 a)

Constraining variable	Conditioning variable	FVE	pseudo-F
Size		2.5	4.98 **
Connectivity		3.8	7.67 **
Size	Connectivity	1.7	3.55 **
Size × connectivity	Size + connectivity	0.7	1.51 *
Size + connectivity + size × connectivity		6.2	4.29 **

761 b)

Constraining variable	Conditioning variable	FVE	pseudo-F
Size		0.9	1.80
Connectivity		2.0	4.02 **
Size	Connectivity	1.4	2.76 *
Size × connectivity	Size + connectivity	2.3	4.76 **
Size + connectivity + size × connectivity		5.7	3.90 **

762 c)

Constraining variable	Conditioning variable	FVE	pseudo-F
Size		4.2	1.39
Connectivity		8.5	2.96 *
Size	Connectivity	3.8	1.33

763 d)

Constraining variable	Conditioning variable	FVE	pseudo-F
Size		3.2	1.09
Connectivity		2.3	0.52

766
 767 **Fig. 1** GNMDS ordination plot of total plant species composition in 200 sample plots in 20
 768 habitat patches. Habitat specialists are shown in red italics. Only species with total sub-plot
 769 frequency > 100 are shown. Arrows indicate correlations between the ordination and
 770 environmental variables, with the length of the arrows proportional to the correlation strength.
 771 Some species names were slightly adjusted to avoid overlap. For species abbreviations, see
 772 **Table A1.1.**
