Abstract:	Once common throughout surface waters west of the Rocky Mountains, the Western Ridged Mussel (<i>Gonidea angulata</i> Lea) has been extirpated throughout much of its range (Blevins et al. 2017), and is currently listed as endangered in Canada (COSEWIC 2010), where its northernmost occurrences are thought to be in Okanagan Lake within the southern interior of British Columbia. Recovery plans are legally required for listed species; but for <i>G. angulata</i> , recovery planning is a challenge as little is known about its habitat requirements, particularly within lakes. To be able to recover <i>G. angulata</i> throughout its historic range, we must study lentic as well as lotic habitats. We developed habitat suitability models for <i>G. angulata</i> in Okanagan Lake using snorkel survey data, habitat data, and two complementary classification methods based on the RandomForest algorithm. Both classification methods ranked the top four predictor variables as effective fetch between 1 and 2.25 km, medium-high embeddedness of substrates (25 - >75%), high proportion of sand in the substrate, and low slope (0-20 %). In comparison, <i>G. angulata</i> habitat in river systems have been described as having low sediment accumulation, boulders that offer refuge, low flow variability, and bank stability. These findings suggest that the drivers for <i>G. angulata</i> distribution in lakes are similar to those in rivers, although predictor variables themselves may vary. This is important because simply using predictor variables from lotic systems would not correctly predict <i>G. angulata</i> occurrence in lakes, demonstrating the importance of this lake-specific investigation.

4 **Abstract**
5

6 Once common throughout surface waters west of the Rocky Mountains, the Western Ridged
7 Mussel (*Gonidea angulata* Lea) has been extirpated throughout much of its range (Blevins et al.
8
9 2017), and is currently listed as endangered in Canada (COSEWIC 2010), where its
10
11 northernmost occurrences are thought to be in Okanagan Lake within the southern interior of
12
13 British Columbia. Recovery plans are legally required for listed species; but for *G. angulata*,
14
15 recovery planning is a challenge as little is known about its habitat requirements, particularly
16
17 within lakes. To be able to recover *G. angulata* throughout its historic range, we must study
18
19 lentic as well as lotic habitats. We developed habitat suitability models for *G. angulata* in
20
21 Okanagan Lake using snorkel survey data, habitat data, and two complementary classification
22
23 methods based on the RandomForest algorithm. Both classification methods ranked the top four
24
25 predictor variables as effective fetch between 1 and 2.25 km, medium-high embeddedness of
26
27 substrates (25 - >75%), high proportion of sand in the substrate, and low slope (0-20 %). In
28
29 comparison, *G. angulata* habitat in river systems have been described as having low sediment
30
31 accumulation, boulders that offer refuge, low flow variability, and bank stability. These findings
32
33 suggest that the drivers for *G. angulata* distribution in lakes are similar to those in rivers,
34
35 although predictor variables themselves may vary. This is important because simply using
36
37 predictor variables from lotic systems would not correctly predict *G. angulata* occurrence in
38
39 lakes, demonstrating the importance of this lake-specific investigation.

4 **Introduction**
5
6
7
8

9 *Gonidea angulata* Lea, the Western Ridged mussel (also known as the Rocky Mountain ridged
10 mussel; family Unionidae) is among the most endangered animal taxa in North America (Bogan
11 1993, FMCS 2016). For conservation efforts to be successful for this species, all habitat types
12 and requirements must be understood. All studies regarding this species' habitat, thus far, have
13 been conducted in river environments, but much of its population occurs in lakes in British
14 Columbia (B.C.), Canada. In the Okanagan Valley, B.C., *G. angulata* occurs in four lakes and
15 the river connecting them, the Okanagan River. This paper presents the first habitat suitability
16 study for *G. angulata* in a lake environment.

27
28
29
30

31 Once prevalent from British Columbia (BC), south to California and eastward to Idaho and
32 Nevada, *G. angulata* has been largely extirpated from its original range for reasons including,
33 but not limited to, human development, industrial contamination of waterways, habitat loss,
34 invasive species, and loss of host fish (Downing et al. 2010, Jepsen et al. 2010, Stanton et al.
35 2012). Similar pressures have negatively impacted other freshwater mussels in North America
36 (e.g., Bauer 1988, Dudgeon 2006, Downing et al. 2010) highlighting the need for increased
37 efforts on the part of researchers and policy makers alike to devise successful conservation
38 management strategies for mussel taxa (Fisheries and Oceans Canada 2010, 2011). Of the
39 various North American species of freshwater mussels, *G. angulata* is considered at most risk of
40 extinction in many places (Blevins et al. 2017), yet very little is known about its habitat
41 requirements. Management strategies require reliable information regarding the habitat
42 requirements and preferences of the target species (Fisheries and Oceans Canada 2010, 2011,

65

1
2
3
4 Stanton et al. 2012). Conservation should be science based, yet up to this point very little was
5
6 known about *G. angulata*'s lacustrine habitat requirements.
7
8
9

10
11 Most studies of *G. angulata* habitat requirements pertain to riverine environments; of all of the
12
13 twenty-eight papers we reviewed in the literature, none of them focused on *G. angulata* in lakes.
14
15 In river environments, important habitat characteristics include low hydraulic variability, flow
16
17 refugia (i.e., boulders), stable substrate, substrate size and distribution, and low sediment
18
19 accumulation (e.g., Vannote and Minshall 1982, Allen and Vaughn 2009, Daraio et al. 2012,
20
21 Davis et al. 2013). Although some of these river characteristics and their functional significance
22
23 may be transferable to understanding lake environments, river and lake environments are
24
25 inherently very different.
26
27
28
29
30

31
32
33 During early stages in their development, freshwater Unionoidea (hereafter referred to as
34
35 mussels) are obligate parasites on fish (Bogan 1993, Vaughn and Taylor 2000). Field data from
36
37 Okanagan Lake suggests the primary host fish for *G. angulata* are sculpin (*C. asper* Richardson,
38
39 1836 and/or *C. cognatus* Richardson, 1836) (Mageroy et al. 2015), along with a few other
40
41 potential host species (Stanton et al. 2012, Mageroy 2015). Because sculpins are very widely
42
43 distributed in Okanagan Lake, host fish are unlikely to be a factor limiting *G. angulata* in this
44
45 system.
46
47
48
49
50

51
52
53 Unionids, including *G. angulata*, spend a large part of their lives either completely or partially
54
55 buried within substrates. Fine substrates are necessary for mussels to bury and to anchor
56
57 successfully (Vannote and Minshall 1982), but oxygen must also be able to permeate this
58
59
60
61
62
63
64
65

1
2
3
4 substratum. In high-energy environments where water turbulence and scouring forces increase
5
6 substrate mobility, stable refugia are required to protect mussels from becoming dislodged or
7
8 crushed by cobble (Davis et al. 2013). Thus, factors which affect substrate composition and
9
10 mobility (e.g., wave action, slope) also directly or indirectly impact mussel distribution (Cyr
11
12 2009, Davis et al. 2013). It is likely there will be many key factors defining the distribution of
13
14 this species in lakes. Within lake shorelines or stream segments, the dominant influence may be
15
16 substrate size distribution and embeddedness, presence or absence of macrophytes, and flow
17
18 refugia (Strayer 2014).
19
20
21
22
23
24
25

26 This paper presents the first habitat suitability study of *G. angulata* in a lake
27
28 environment. Here, we use extensive field survey data to develop a habitat suitability
29
30 model for *G. angulata* in Okanagan Lake, based on recent presence/not detected
31
32 populations (Figure 1; COSEWIC 2010, Stanton et al. 2012). We also seek a better
33
34 understanding of *G. angulata*'s ecology, and in particular the factors that influence its
35
36 geographic distribution. Our *a priori* hypotheses are: *G. angulata* are not distributed
37
38 randomly, and useful predictors of its distribution include substrate type and
39
40 embeddedness, low shoreline slope, and site exposure.
41
42

48 **Methods**

49
50
51
52

53 *Study Area*

54
55 The Okanagan Valley is located in south-central British Columbia and is surrounded by
56
57 three mountain ranges: the Columbia Mountains lie to the east, the Cascade Mountains
58
59
60
61
62
63
64
65

1
2
3
4 lie to the south-west, and the Coast Mountains are found to the west. Following a north-
5 south fault, the Okanagan Valley was deeply carved into bedrock by recent successive
6
7 south fault, the Okanagan Valley was deeply carved into bedrock by recent successive
8
9 glaciations. The valley is occupied by a series of lakes, the most northern one, Okanagan
10
11 Lake, being the focus of our study. Okanagan Lake drains south into the Okanagan
12
13 River, which connects a series of lakes at the southern end of the valley, before
14
15 continuing on to join the Columbia River in the U.S.A.
16
17
18
19
20

21 This valley is part of the Montane Cordillera Ecozone. It is a semi-arid region with
22
23 precipitation ranging from 27.5 cm/yr in the south to 44 cm/yr in the north. Extreme high
24
25 summer air temperatures reach 41°C and extreme winter cold temperatures can reach -
26
27 27°C (Stockner and Northcote 1974).
28
29
30

31
32
33 Okanagan Lake (50°0'N, 119°30'W) is long and narrow, approximately 120 km long
34
35 and 3.5 km (average) wide (Figure 1; Stockner and Northcote 1974). Its watershed
36
37 encompasses 6178 km² (Roed 1995), with a maximum depth of 232 m and an average
38
39 depth of 76 m (Stockner and Northcote 1974). Lake level fluctuates annually from ± 0.5
40
41 m to ± 0.9 m (in 2009 - 2010; Stanton et al. 2012). Shoreline length is 290 km. The
42
43 majority of the watershed surrounding Okanagan Lake is forested, with some adjacent
44
45 communities and cities.
46
47
48
49
50

51
52
53 Okanagan Lake is a warm monomictic lake (i.e., stratified in summer, and ice-free in
54
55 winter) (Stockner and Northcote 1974), with surface water temperatures ranging from
56
57 1.7 to 23.0°C (Mackie 2010). It is an oligotrophic lake (Stockner and Northcote 1974),
58
59
60
61
62
63
64
65

1
2
3
4 with high dissolved oxygen, calcium and alkalinity, and low total nitrogen and
5
6 phosphorus (Mackie 2010, BC Ministry of Environment 2001). Water pH is circum-
7
8 neutral to alkaline (pH 7.9 to 8.7) with specific conductance ranging from about 220 to
9
10 330 $\mu\text{S}/\text{cm}$ (e.g., Pinsent and Stockner 1974). The water residence time is very long
11
12 (approximately 60 to 70 years).
13
14

15 16 17 18 19 *Explanatory variables*

20
21 We used an *a priori* approach to select relevant variables for habitat suitability model
22
23 construction. Based on scientific literature and expert opinions, we included the
24
25 following variables in our predictive models: percentages of boulder, sand,
26
27 embeddedness, and foreshore slope. These variables were chosen based on previous
28
29 significance in mussel occurrence studies. For example, boulders can provide refuge and
30
31 microhabitats important for mussels, while sand grain sizes allow for mussel anchorage
32
33 in the substrate (Strayer 2014), and low embeddedness is related to low sediment
34
35 accumulation, which is significant in river environments with *G. angulata* present (Allen
36
37 and Vaughn 2009). The slope of a site can explain interactions between lake bottom and
38
39 wave action, and subsequent sediment accumulation and substrate composition
40
41 (Hakanson 1977). Most of the identified variables included in the model came from pre-
42
43 existing Foreshore, Inventory and Mapping (FIM) data from Okanagan Lake (Schleppe
44
45 and Mason 2009). In this methodology, shore zone is defined as the deep water regions
46
47 of the lake to 30 to 50 m past the high water level, reaching into the upland/riparian zone
48
49 (Schleppe and Mason 2009).
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 To better characterize the sites, several new variables were added to supplement the FIM
5
6 data. These included several abiotic attributes: total fetch, geomorphic description (e.g.,
7
8 cusplate foreland, alluvial fan, crag, beach, bay, cove, breakwater, bank, and a river
9
10 mouth), presence of an underwater ledge, shoreline morphometry (i.e., degree of
11
12 concavity/convexity), clay, and depth of dissolved oxygen penetration into substrate
13
14 (e.g., by depth of oxidization on rebar stakes).
15
16
17
18
19
20

21 Fetch is a measure of site exposure to predominant winds (Hakanson 1981, Callaghan et al.
22
23 2015). Effective fetch, also known as total fetch, was included in the data as a proxy for wave
24
25 action, turbulence, disturbance, nutrient movement, and dissolved oxygen at each site (Hakanson
26
27 1977, Cyr 2009), and was calculated using the Wind Fetch Tool. Atmospheric data from
28
29 government weather stations (www.windfinder.com) were collected for five stations bordering
30
31 Okanagan Lake describing average historical wind origins. Fetch was calculated as a weighted
32
33 average fetch for each season (spring, summer, autumn, and winter).
34
35
36
37
38
39

40 Geomorphic characterizations of sites have been effective in mussel studies (e.g., Vannote and
41
42 Minshall 1982, Gangloff and Feminella 2006), and may have been useful in predicting mussel
43
44 occurrence in certain bathymetric and topographical features in this lake. During field surveys,
45
46 an underwater ledge was observed in many of the sites surveyed. This lead to the hypothesis that
47
48 perhaps this feature played a role in predicting mussel presence. The degree of shoreline
49
50 morphology, explained in part by interactions with wind and longshore currents (e.g., Burrows et
51
52 al. 2008), may have illustrated at what, if any, specific threshold mussel habitat exists in certain
53
54 shoreline shapes. Clay substrate has very low permeability for oxygen. Lake bottom which is
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 clay dominant near the upper layers was hypothesized to be unsuitable for mussels, since clay
5
6 would cut off oxygen supply to buried mussels. Furthermore, experimental data on depth of
7
8 oxygen permeation into the substratum was included, as shallow oxygen permeation is likely a
9
10 limiting factor for mussel occurrence.
11
12
13
14

15
16 This *a priori* variable selection approach also informed site selection, by enabling a stratified
17
18 sampling design to increase the likelihood of observing *G. angulata* within the lake. The strata
19
20 included the entire range of the selected variables. For example, although low substrate
21
22 embeddedness was hypothesized to be a predictor for presence of this species, sites with medium
23
24 and high embeddedness were also included in the model. This was the case for substrate
25
26 embeddedness, boulders, slope, and sand. In stratified random sampling, locations within the
27
28 strata are themselves randomly selected.
29
30
31
32
33
34

35 36 *Site selection*

37
38 The sites selected were distributed throughout the littoral zone of Okanagan Lake, to include all
39
40 potential habitat types and to avoid distance-related interactions between sites. No sites were
41
42 located in the middle of the lake.
43
44
45
46
47

48 For the model, all 19 sites in Okanagan Lake where *G. angulata* had been reported
49
50 (between 2005 – 2012) were included. The variables identified by the expert consultation
51
52 process were then used to target 26 additional sites, selected in accordance with a
53
54 stratified sampling approach to increase the likelihood of encountering this
55
56 inconspicuous species. A random number generator was used in GIS (ESRI, 2011) to
57
58
59
60
61
62
63
64
65

1
2
3
4 locate these sites. Thus, this model is based on stratified random sampling. This resulted
5
6 in a total of forty-five survey sites along the shoreline of Okanagan Lake. Selected sites
7
8 included north, central, and southern sections of the lake. Sites not accessible by road
9
10 were accessed by boat. This study was limited to 45 sites due to effort constraints, while
11
12 still maintaining a sufficient sample size.
13
14

15 16 17 18 19 *Mussel and host fish surveys*

20
21 Surveys to detect *G. angulata* populations (presence/not detected) at all 45 sites were
22
23 conducted according to standard methods for rare freshwater mussel species (Smith
24
25 2006, Mackie et al. 2008, Stanton et al. 2012). Snorkel surveys were conducted at every
26
27 site included in this model between June – August in 2014. A minimum of two
28
29 snorkelers swimming beside each other, made parallel sweeps along the shoreline.
30
31 Sweeps progressed to greater depths once the entire length of the site was reached, with
32
33 a maximum survey depth of approximately 4 m. Sites with steep slopes generally limited
34
35 the distance from shore the parallel snorkelers could survey, since depths of 4 m
36
37 occurred quicker at these gradients than at more moderately sloped sites. The length of
38
39 the selected sites varied greatly, from 110 m to 6250 m. This was a limitation of the
40
41 existing FIM database, where site lengths were pre-determined based on foreshore type,
42
43 categorized by Schleppe and Mason (2009). Presence/not detected data on *G. angulata*
44
45 were recorded at every site. Although it is possible mussels may occur deeper than 4 m,
46
47 we were not able to observe them at depths greater than this, even while diving below
48
49 the surface.
50
51
52
53
54
55
56
57

14

15 16 *Constructing the habitat suitability model* 17

18
19 Two classification packages using random forests (RF) in R 3.1.2 (R Core team, 2014)
20
21 were used to generate a habitat suitability model; RF and Party packages. RF accounts
22
23 for correlations and variable interactions, and ranks interactions between variables by
24
25 importance (Chen and Ishwaran 2012). A tuning parameter, ‘mtry’, is altered within the
26
27 RF package; denoting the number of predictor variables chosen to create a tree derived
28
29 from the partitioned response. High classification accuracy has been shown in presence-
30
31 absence ecological data using RF (Cutler et al. 2007).
32
33
34
35
36
37

38 The RF package iterations were run multiple times with data reductions, to produce a
39
40 model with the lowest average misclassification rate (Grömping 2009, Strobl et al.
41
42 2009). Each model run generated 5000 trees of 100 iterations each in a sensitivity
43
44 analysis, with ‘mtry’ ranging for each series from 2 (minimum) to 6. The data were also
45
46 run through the classification package Party, developed by Hothorn et al. (2006), to
47
48 assess correlation among predictor variables and to facilitate a comparison and validation
49
50 of results between the two classification packages.

Variable importance was assessed using the mean decrease in accuracy (MDA), which was determined by normalizing the difference between the classification accuracy for variable data ‘observed’ and the classification accuracy for the variable randomly permuted (Cutler et al. 2007). The higher the value of the mean decrease in accuracy, the more important the variable is within the classification (Cutler et al. 2007).

Results

Mussel Surveys

Mussel surveys resulted in six new occurrence sites for *G. angulata*. One of these new sites had only 1 live *G. angulata* observed in the 4 km shore length, as well as 1 shell. *G. angulata* are distributed in the north, central, and south of Okanagan Lake, as well as on both the east and west sides of the lake. Additionally, *Anodonta*, another native freshwater mussel was observed throughout the lake, and *Margaritifera falcata* was observed in Mission Creek, a tributary of Okanagan Lake. Sculpin (*Cottus* sp.), the primary host fish for *G. angulata*, were observed at all 45 sites.

Random Forest model

The use of four predictor variables yielded the lowest misclassification rate (Out-of-bag error; OOB) of 24.2 %, with ‘mtry’ tuned to 2 (using the randomForest function for package RandomForest). In comparison, ‘mtry’ tuned to 3 had a higher misclassification rate of 25.8 % with the top four predictor variables in the RandomForest package. While many other variables (e.g., substrate grain sizes: fines (< 0.06 mm), fine gravel (2 – 16 mm), coarse gravel (16 – 64 mm), fine cobble (64 – 128 mm), coarse gravel (128 – 256 mm), aquatic vegetation, groynes (i.e., any perpendicular structure to shoreline impacting regular sediment drift), cliffs, littoral zone width, docks, etc.) were incorporated into preliminary models, these were not influential in explaining *G. angulata*’s distribution in Okanagan Lake. With 38 variables (chosen based on the expert consultation process), the OOB error was 23.26%. Many of these variables were eliminated based on the MDA measures of variable importance, which ranked significantly

1
2
3
4 lower than the top ranked predictor variables. Top predictors MDA were greater or equal to 18,
5
6 while all other variables consistently ranked less than 8.

7
8
9 The variable importance function ‘varimp’ in the Party package supported the RandomForest
10
11 results, which illustrated variables with lower MDA were correlated and added no meaning to
12
13 the rest of the model.
14

15 16 17 18 19 *Geomorphic and Biotic controls on G. angulata*

20
21 The RF package outputs were used to create variable partial dependence plots (Figure 2).

22
23 Partial dependence plots illustrate the probability of *G. angulata* occurrence based on
24
25 one predictor variable in the best model, after averaging out the effects of all other
26
27 predictor variables (Cutler et al. 2007).
28

29
30 The most important habitat variables for *G. angulata*, as identified by both models, were
31
32 high embeddedness of substrates (>75%), sand (0.06 – 2 mm) occurrence (>20%),
33
34 followed by total fetch (>1 km and < 2.25 km), and bench or low slope.
35
36
37

38
39
40 Within the Party models, boulder (> 256 mm) occurrence was determined to be a
41
42 correlated variable, but was an additional important predictor within the RF models.

43
44 These results support our *a priori* hypotheses (i.e., that *G. angulata* is not distributed
45
46 randomly; substrate type, low-moderate slope, and fetch are identified as useful
47
48 predictors of *G. angulata* occurrence). Low embeddedness of substrates was negatively
49
50 associated with *G. angulata* habitat, thus this habitat characteristic was not included in
51
52 the final model.

Constructing the habitat suitability model

We applied these results, from the 45 sites analyzed in the RF packages, to the rest of the Okanagan Lake foreshore. The optimal model was used to generate a vector map of mussel habitat distribution from FIM data using QGIS 2.18.7 (Figure 1). Layers used within the FIM included the most favorable habitat ranges of embeddedness, slope, sand, and boulders, in addition to a ‘mussels’ (known presence) layer. Sites were ranked as best, good, and poor model fit, based on the presence of top predictor variables.

Due to the spatial generalizations involved in converting between raster and vector formats during the implementation of the wind fetch tool, fetch could not be calculated for twelve sites out of the entire circumference (314 sites) of Okanagan Lake (Munshaw 2016). Their fetch was then calculated by averaging the fetch for adjacent sites. Of these sites, five contain top predictor categories, suggesting they may offer suitable habitat for *G. angulata* (Table 1, Figure 2). One site was included as a best model fit, while four were included as good model fits.

Throughout the circumference of the lake (314 sites, 290 km), 27.3 percent (n = 3) of the sites with best model fit have known *G. angulata* occurrences (Table 1). Best model fit represents a mere 11 sites throughout the lake, and 5.99 km. No sites of Good fit (15.2 km) contain *G. angulata*, while 8 percent (n = 22) of Poor fit sites do. The majority of Okanagan Lake represent Poor model fit for *G. angulata* habitat; 268 km.

Discussion

Mussel surveys

Importantly, in our study, sites with over 300 *G. angulata* are weighted the same as a site with only 1 mussel found. All sites with a minimum of 1 mussel are considered

1
2
3
4 occurrence sites. Since mussels spend the majority of their lives either completely or
5
6 partially buried, we assumed sites with only 1 mussel observed likely contained many
7
8 more individuals that were not found. Conversely, sites with no mussels found may also
9
10 have been occurrence sites. This is a limitation of our presence/not detected study
11
12
13 design.
14

15 16 17 18 19 *Geomorphic and Biotic controls of G. angulata*

20
21 Interestingly, low embeddedness was negatively associated with *G. angulata* habitat,
22
23 thus this habitat characteristic was not included in the final model. Embeddedness is
24
25 often used to assess macroinvertebrate habitat (Sylte and Fischenich 2002). Mussels tend
26
27 to inhabit interstitial spaces in streambed (and littoral zone) substrate; areas with high
28
29 embeddedness levels subsequently decrease space between substrates, and therefore
30
31 decrease available habitat.
32
33
34
35

36
37
38 Our results show that medium-to- high embeddedness is a positive attribute, while low
39
40 embeddedness is a negative habitat attribute for *G. angulata* in Okanagan Lake. We were
41
42 surprised by the positive impact of high substrate embeddedness (70-100%). High
43
44 embeddedness could result in the clogging of mussel gills; thus, it is not necessarily
45
46 associated positively with *G. angulata* in river habitats (Bogan 1993, Brim Box et al.
47
48 2002). Organic matter may be included in the fine sediment components contributing to
49
50 embeddedness and, through decomposition, may institute a locally hypoxic or anoxic
51
52 environment in the sediments. Thus, high embeddedness often limits the areal extent of
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 habitat within which many fish, macroinvertebrates and periphyton may live (Sylte and
5
6 Fischenich 2002).
7
8
9

10
11 The texture of the embedding materials may also be important. It would be useful to
12
13 contrast sites where the embedding materials are coarse (sand) versus fine (clay/silt)
14
15 sediments. The difference in the embeddedness effect between studies might be
16
17 explained by the very different hydrodynamic properties of these systems. In lotic
18
19 environments, water movement enables finer sediments and organics to continually
20
21 move downstream, delivering a constant supply of food to mussels. In lentic habitats,
22
23 significant wind and wave action is required to transport these fine materials. Higher
24
25 embeddedness in Okanagan Lake, could be associated by higher food availability; lower
26
27 embeddedness (0-20%) may be associated with lower food availability. In addition, since
28
29 Okanagan Lake is exposed and well-mixed (Hyatt and Stockwell 2003), high oxygen
30
31 concentrations are maintained throughout the littoral benthic environment. Thus, oxygen
32
33 depletion in areas with high embeddedness may not be a problem in Okanagan Lake.
34
35
36
37
38
39
40
41
42

43 Medium or high embeddedness may also be associated with greater sediment stability in
44
45 low energy environments (Brim Box et al. 2002). *Gonidea angulata* has a well-
46
47 developed siphon and individual mussels appear to maintain a mostly buried positioned
48
49 where filtering functions may be little affected; thus, making them suitable inhabitants of
50
51 fine sediment and sand (Vannote and Minshall 1982).
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 In agreement with earlier studies, increasing sand at a site is positively associated with
5
6 *G. angulata* habitat (Vannote and Minshall 1982) in Okanagan Lake. Sand provides a
7
8 suitable medium within which *G. angulata* may bury (Vannote and Minshall 1982,
9
10 COSEWIC 2003, Davis et al. 2013, Strayer 2014) without inhibiting their movement.
11
12
13
14 Sand will also more readily allow oxygen to penetrate into the substrate, whereas clay or
15
16 silt will impose a barrier preventing oxygen exchange with overlying water.
17
18
19
20

21 The positive association of mussels with boulders can be explained via the refuge and stability
22
23 they offer, but their presence are not an essential part of suitable habitat at each site. The positive
24
25 association with boulders may be explained by the fact that they provide micro-eddy
26
27 environments beneath them, supplying oxygen and organic matter and a depositional
28
29 environment suitable for anchoring the mussel (Davis et al. 2013), or possibly that they impeded
30
31 the ability of invasive macrophyte management via rototilling, thus offering the mussels refuge
32
33 from this activity. Invasive macrophytes are partially managed in Okanagan Lake by rototilling.
34
35 Live *G. angulata* were present in 25% of the rotoation polygons in the Okanagan Valley, B.C.,
36
37 in a recent experimental study (Mageroy et al. 2017).
38
39
40
41
42

43 Boulders function as refuge from predators, shear stress and scouring. However, boulders were
44
45 found to be a highly correlated variable with the other predictor variables, adding instability to
46
47 the model in RandomForest, and were not included in the Party output. The importance of
48
49 boulder occurrence likely depends on site exposure. In more exposed sites, boulders provide the
50
51 low energy microhabitat that aggrades sand, which we have demonstrated is important to *G.*
52
53 *angulata* in Okanagan Lake. We infer that microhabitats among boulders may be more important
54
55 at sites with higher effective fetch.
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7 Our results show that a fetch between 1 km and 2.25 km is most favorable for *G.*
8
9 *angulata*, while the probability of *G. angulata* occurrence decreases at shorter and longer
10
11 fetches (Figure 2). This suggests a moderately energetic environment is most suitable for
12
13 these mussels. Fetch may also serve as a proxy for longshore current velocities. In
14
15 Canada, *G. angulata* occur in two additional lakes within this watershed south of
16
17 Okanagan Lake (i.e., Skaha Lake and Vaseux Lake), as well as historically in Osoyoos
18
19 Lake. The dimensions of these lakes are narrow, like Okanagan Lake, but are much
20
21 shorter, i.e., each lake has a shorter fetch than Okanagan Lake. Vaseux Lake is arguably
22
23 an extension (a wide section) of Okanagan River, in terms of its hydrodynamic
24
25 properties. Elsewhere, *G. angulata* is principally a riverine species (Frest and Johannes
26
27 1995, Taylor 1981, Nedeau *et al.* 2005); lentic populations may be associated with
28
29 exposed sites where wind and waves yield analogous conditions. Longshore currents are
30
31 expected to be stronger, and wave action greater, both at the surface and internally (in the
32
33 thermocline), at the most exposed sites (greatest fetch).
34
35
36
37
38
39
40
41
42

43 Currents and wave action also shape the patterns of erosion and sediment redistribution
44
45 in lakes, and thus the embeddedness and substrate composition at each site. A very long
46
47 fetch can contribute to scouring, bed shear stress, excess turbulence, and removal of the
48
49 fine sediments necessary for burying mussels, ultimately promoting substrate instability
50
51 (Hakanson 1977, Cyr 2009). Mussels, especially the juvenile mussels, may be eroded
52
53 and transported away from exposed sites during scouring events (Cyr 2009) or crushed
54
55 by large, mobile substrate elements (Strayer 1999).
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7 Exposed, high energy sites (large fetch) may enhance the delivery of food (plankton),
8
9 nutrients, and dissolved oxygen to littoral benthic communities (e.g., Cyr 2009). It is
10
11 likely these effects explain the relationship between fetch and *G. angulata* occurrence in
12
13 Okanagan Lake (Figure 2). At a fetch lower than 1 km, the lower probability of *G.*
14
15 *angulata* occurrence may be attributable to a reduced supply of food (plankton),
16
17 nutrients, and dissolved oxygen. Very few sites exist in Okanagan Lake with fetch lower
18
19 than 1 km (10 sites exist out of 314), which may also explain why no mussels are found
20
21 in this habitat type. At exposures greater than 2.25 km increased turbulence results in
22
23 removal of fine substrates, substrate instability and, potentially, direct damage to and/or
24
25 dislocation of the mussels. In Okanagan Lake, the “Goldilocks” zone in terms of fetch
26
27 appears to lie between 1 and 2.25 km, where fetch is sufficient to supply food, oxygen
28
29 and nutrients, without excessive scouring of the shoreline.
30
31
32
33
34
35
36
37

38 We found that a bench feature or low slope (i.e., less than 5% gradient) was positively
39
40 associated with *G. angulata* occurrence (e.g., bench vs. steeper slopes > 60%). A bench
41
42 shoreline is one that rises, typically very steeply, has a flat area typically greater than 15
43
44 horizontal meters, then becomes steep or very steep again (Schleppe and Mason 2009).
45
46 In Okanagan Lake, foreshores with categorical bench slopes are uncommon (4 such sites
47
48 exist), while 132 have low slope. The importance of bench and low gradient sites for *G.*
49
50 *angulata* occurrence may be linked to the turbulence arising from waves as they interact
51
52 with the lake bottom. Wind and waves interact differently at sites with different littoral
53
54 slopes. At steeper sites no fine material is deposited (Hakanson 1977). At lower slopes,
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 mussel anchorage may be possible in a fine material depositional environment, within an
5
6 optimal fetch range.
7
8
9

10 11 *Management implications*

12
13
14 We applied our results, from the 45 sites analyzed and discussed above, to the entire Okanagan
15
16 Lake shoreline. Sites with the top four predictor variables for *G. angulata* occurrence are
17
18 considered the best fit with this model, and top priority for conservation within Okanagan Lake
19
20 (Table 1, Figure 1; Red). Of these ten sites, three are known to contain *G. angulata* (located in
21
22 Summerland, BC). Note that all the *G. angulata* sites within Okanagan Lake, with the exception
23
24 of one site (in Penticton, date of occurrence unknown), are recent (2005-2015) records. There are
25
26 existing foreshore segments which are currently protected (Figure 1), and overlap with many, but
27
28 not all of the occurrences of *G. angulata*.
29
30
31
32
33
34
35

36 Like most animals, these mussels have ranges within these important habitat characteristics that
37
38 are tolerable. For example, even though a medium embeddedness measure at a site is the best
39
40 predictor for this species, high embeddedness sites also positively predict mussel occurrence
41
42 (Figure 2). Therefore, for future surveys, sites with appropriate categorical and fetch values
43
44 should also be considered a good model fit, and high priority habitat for ground-truthing for this
45
46 mussel. Sites that contain combinations of these ranges (Figure 2): Medium-High embeddedness,
47
48 Medium and Very High sand, fetch > 1.0 km and < 3.28 km, with Low slope are considered
49
50 good model fit and high priority habitat (Table 1). Sites that were not ranked as best or good fit
51
52 were listed as low priority for the rest of Okanagan Lake.
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 Sites which contain the most favorable ranges for important variables (i.e., are ranked as best and
5
6 good model fit), are recommended for ground-truthing of this species (Table 1). These sites are
7
8 situated throughout the length of the lake (Figure 1). Sites with the best model fit are
9
10 recommended as locations for preservation, while the new occurrences of *G. angulata* should be
11
12 included in the protected foreshore.
13
14
15
16
17
18

19 This novel work is important for understanding the relationships between this species'
20
21 occurrence and its lake-specific habitat requirements. In large systems, such as Okanagan Lake,
22
23 where survey effort is often limited by time and financial constraints, and by the
24
25 characteristically patchy distribution of mussel populations, targeting sites for ground-truthing
26
27 and conservation is invaluable.
28
29
30
31
32

33 *Future research*

34
35
36 This study outlines the framework for building a habitat suitability model for this species.
37
38 Habitat suitability models based on presence/not detected data are built with the assumption that
39
40 sites where the species is undetected (i.e., “no detection” sites) are sites where the mussels are
41
42 truly absent; a difficult claim to make, especially for inconspicuous species which are buried for
43
44 the majority of their lives. For a greater understanding of this species' habitat preferences and
45
46 habitat suitability, exploring *G. angulata* abundance, density, and/or population age structure at
47
48 these sites is required. The usefulness of this model is reflected by the number of sites where *G.*
49
50 *angulata* were correctly predicted to exist, in a very large system. Similar models characterising
51
52 habitat requirements for other mussel species can be built using this approach.

Wilson (MOE). We thank MOE for sharing the Wind Fetch Tool data for fetch values for the entire circumference of Okanagan Lake. Robin Munshaw (Simon Fraser University) was the Geographic Information Systems technician who implemented the wind fetch tool in GIS 10.0. Financial support was provided by BC Ministry of Forests, Land, Natural Resource Operations, and Rural Development; MFLNRORD, the Pacific Northwest Shell Club, and the University of British Columbia.

The consulted freshwater ecology experts included: Jon Mageroy (Norwegian Institute for Nature Research), Ian Walker (University of British Columbia, Kelowna, B.C.), Jeff Curtis (University of British Columbia, Kelowna, B.C.), Robert Plotnikoff (Tetra Tech. Inc., Bellevue, WA), and Shelly Miller (Oregon Department of Fish and Wildlife, Corvallis, OR).

Roxane Snook and Jon Magerøy conducted field work, with technical and taxonomic identification advice from Lora Nield. Roxanne Snook led manuscript writing with substantive editorial input from all; Jeff Curtis, Jason Pither, Ian Walker, Jon Magerøy, and Lora Nield. Jason Pither wrote the sensitivity analysis code, and advised on all statistical analyses.

4 Figure 1. Map of Okanagan Lake and sites with their associated fit for this model's habitat
5 suitability for *G. angulata* (Table 1); based on the 45 sites surveyed and analyzed in this study
6 design, which are then extrapolated across the lake's entire shoreline. The best fitted sites with
7 this model are illustrated in red, while sites with a good fit are blue, and foreshore of Okanagan
8 Lake that is currently protected are illustrated with a green buffer (data from MFLNRORD,
9 2017). Sites with known occurrence of *G. angulata* are illustrated by black triangles, while sites
10 surveyed without their detection* are empty triangles (image from Snook 2017, modified and
11 used with permission).

65

Partial dependence plots of each variable. Plots indicate probability of *G. angulata* occurrence based on each predictor variable in the best models, after averaging out the effects of all other predictor variables in the model. Embeddedness is an ordinal variable including low (0-25%), medium (25-75), and high (>75%) categories. Total fetch (effective fetch, km) is a continuous measure. Sand is an ordinal variable including none, low (1-20%), medium (25-40%), high (45-60%), and very high (70-100%). Slope is an ordinal variable including categories bench (a shoreline that rises, typically very steep, has a flat area typically greater than 15 horizontal meters, then becomes steep), low (0-5 %), moderate (5-20 %), steep (20-60 %), and very steep (60+ %).

TABLE 1. Sites ranked in accordance with how well they fit this model, using the top four predictor variables. Also provided are variable ranges reflecting the tolerance of this species. For example, for best model fit the most common variable ranges comprise high or medium embeddedness, high sand, a mean fetch of 1.89 km, and low slope. All sites that did not fit as best, or good, are ranked as poor fit. The number of sites represented by each rank are listed for comparison to the 314 total sites on the foreshore of Okanagan Lake.

Model Fit*	Embeddedness	Sand	Fetch (km)	Slope	Sites	Sites with <i>G. angulata</i> (%)	Foreshore Length (km)
Best	H or M	H	1.89	L	11	27.3	5.992
Good	H or M	VH or M	1.64	L	24	0	15.280
Poor	M	N or L	2.18	L	279	8	268.040

Abbreviations: Very High (VH), High (H), Medium (M), Low (L), None (N)

*Model fit is based on the variable partial dependence plots illustrated in Figure 2, from the model with the lowest misclassification rate of 24.2%. Sites containing the most to least predictive category of each variable are ranked from highest (best) to lowest (poor).
