37 ABSTRACT.—Agriculture and development have caused landscape change throughout the
38 southwestern Great Plains in the range of the lesser prairie-chicken (*Tympanuchus*
39 *pallidicinctus*). Landscape alteration within the lesser prairie-chicken range may
40 contribute to range contraction and population losses through decreases in survival rates.
41 Our objectives were to determine if (1) landscape configuration (*i.e.*, the spatial
42 arrangement of habitat) or composition (*i.e.*, the amount of habitat), at the study-site
43 scale, affected annual survival of females, (2) relationships exist between landscape
44 context (*i.e.*, landscape configuration and composition) and weekly survival to assess
45 effects of landscape composition and configuration on lesser prairie-chicken populations,
46 and (3) anthropogenic features influenced daily mortality risk. We captured 170 female
47 lesser prairie-chickens and used very-high-frequency and GPS (Global Positioning
48 System) transmitters to track their movement and survival for 2 y. We used known-fate
49 survival models to test if landscape configuration or composition within three sites in
50 Kansas were related to differences in female survival among sites. In addition, we tested
51 for relationships between weekly survival and landscape configuration or composition
52 within home ranges. Finally, we used Andersen-Gill models to test the influence of
53 distance to anthropogenic features on daily mortality risk. Differences in survival were
54 evident between sites with differing landscape compositions as annual survival in
55 Northwestern Kansas ($\hat{S} = 0.27$) was half that of Clark County, Kansas ($\hat{S} = 0.56$), which
56 corresponded with 41.9% more grassland on the landscape in Clark County; landscape
57 configuration did not measurably differ among sites. Survival was greater for prairie-
58 chickens with home-ranges that had greater patch richness, and in areas with 30% crop

59 and 57% grassland. Female lesser prairie-chickens also experienced greater mortality risk
60 closer to fences at patch edges. Further conversion of grassland landscapes occupied by
61 lesser prairie-chickens should be avoided to reduce habitat loss and fragmentation
62 thresholds that could affect survival. We suggest continued encouragement of
63 Conservation Reserve Program enrollment in western areas of the lesser prairie-chicken
64 range to maintain or increase the amount of grassland to increase annual survival.

65 INTRODUCTION

66 Settlement of the Southern Great Plains starting in the latter part of the 19th century
67 caused wide-spread alteration of grassland landscapes, which was accelerated following
68 discovery and large-scale utilization of the Ogallala aquifer by the mid-20th century (Lewis,
69 1990; Coppedge *et al.*, 2001). Landscape fragmentation and habitat loss in the Great Plains,
70 namely loss of grasslands with increasing isolation and reduction in size of grassland patches
71 (Fahrig, 2003), resulted from direct conversion of land from native prairie to agricultural
72 production, including row-cropping or grazing by domestic livestock (Haukos and Boal, 2016;
73 Rodgers, 2016). Quality of remaining grasslands has also declined across time with the alteration
74 of ecological drivers, such as the removal of fire resulting in tree encroachment (Fuhlendorf *et*
75 *al.*, 2002, 2017; Lautenbach *et al.*, 2016; Spencer *et al.*, 2017). Anthropogenic features on the
76 landscape have further fragmented and isolated grassland patches. Power lines, fences, roads,
77 energy infrastructure, and other types of urbanization can affect distribution and space use of
78 prairie birds, creating barriers to movement, reducing habitat availability due to avoidance, and
79 by enhancing conditions for predators to traverse and perceive the landscape, increasing the risk
80 of predation (Pruett *et al.*, 2009; Hagen *et al.*, 2011). With a growing demand for domestic

81 energy, food, and infrastructure, an increase in anthropogenic structures and other landscape
82 changes are persistent, thereby increasing potential negative effects on grassland species
83 (Coppedge *et al.*, 2001; Hovick *et al.*, 2014).

84 The lesser prairie-chicken (*Tympanuchus pallidicinctus*) is considered an umbrella
85 species of the western portion of the Southern Great Plains (Miller *et al.*, 2016), and its
86 conservation could provide ecological benefits to many other species (Hagen and Giesen, 2005).
87 Lesser prairie-chickens traverse large areas, requiring a heterogeneous landscape configuration
88 for all life-history stages (Fuhlendorf and Engle, 2001; Haukos and Zavaleta, 2016; Robinson et
89 al. 2017). Population declines of lesser prairie-chickens have been commensurate with
90 aforementioned losses of prairie habitat (Haukos and Zavaleta, 2016). Quantifying demographic
91 responses to variation in available habitat area, habitat configuration, and anthropogenic features
92 on the landscape are necessary to identify factors contributing to population dynamics.

93 The theoretical foundation underpinning landscape ecology predicts the existence of a
94 threshold of habitat loss, due to both reduction in both quantity and quality, that when exceeded
95 is detrimental to demographic rates (Fahrig and Merriam, 1985; Fahrig, 2001, 2003). Population
96 resilience to habitat loss needs to be considered on a species-specific basis, as a species' life-
97 history dictates responses to landscape fragmentation (Dooley and Bowers, 1998). Alternatively,
98 there may be an optimum landscape context that maximizes species-specific population growth
99 and therefore persistence. However, if an area supports potential habitat and is colonized by a
100 population, but adult survival or reproductive output of the extant population is not sufficient to
101 offset mortality, long-term persistence is unlikely without corresponding immigration (Pulliam,
102 1988). Relationships between population dynamics and landscape features need to be quantified
103 at multiple scales, from individuals to populations, to assess habitat quality (Fahrig and Merriam,

104 1985; Dooley and Bowers, 1998; Chalfoun and Martin, 2007). If relationships exist between
105 lesser prairie-chicken adult survival and landscape configuration (*i.e.*, the spatial arrangement of
106 habitat) or composition (*i.e.*, the amount of habitat and patch types), understanding both direct
107 and indirect drivers of these relationships can also assist to target areas on the landscape for
108 conservation planning, development of management strategies, and assure long-term population
109 persistence (Fahrig, 2002; Mills, 2007; Johnson *et al.*, 2010).

110 Past studies on lesser prairie-chickens have determined patterns of avoidance of power
111 lines, buildings, and, to a lesser extent, paved roads and oil wells (Hagen *et al.*, 2011;
112 Bartuszevige and Daniels, 2016; Grisham *et al.*, 2016b). Further, increasing landscape
113 fragmentation decreases the probability of lek persistence (Woodward *et al.*, 2001). However,
114 few studies have investigated relationships between landscape context (*i.e.*, landscape
115 configuration and composition) and lesser prairie-chicken survival. At a fine scale, some lesser
116 prairie-chicken populations have increased survival with increased shrub cover and vegetation
117 density (Patten *et al.*, 2005). Habitat loss, increased patch isolation, and anthropogenic
118 development also have the potential to negatively affect female lesser prairie-chickens through
119 several mechanisms including both direct mortality (*i.e.*, collision with anthropogenic structures)
120 and indirect mortality (*i.e.*, predator subsidization). Research designed to relate effects of
121 landscape features, composition, and configuration on survival is needed for lesser prairie-
122 chickens. Results of such research will inform future management and conservation actions by
123 identifying whether differences in landscape characteristics are contributing to declines of lesser
124 prairie-chicken populations through effects on annual survival.

125 Lesser prairie-chickens in Kansas occupy three ecoregions with distinct soil and
126 vegetative characteristics and varying degrees of structural fragmentation (McDonald *et al.*,

127 2014; Spencer *et al.*, 2017). The existence of populations of lesser prairie-chickens across the
128 Southern Great Plains in differing landscape configurations and compositions allows for a robust
129 assessment of adult survival as a function of landscape characteristics. Our objectives were to (1)
130 estimate and compare annual lesser prairie-chicken survival among three sites with different
131 landscape contexts, (2) determine relationships between landscape metrics and weekly survival
132 to understand how landscape composition, and configuration, affect lesser prairie-chicken
133 populations, and (3) estimate the effect of distance to anthropogenic features and landcover type
134 on daily lesser prairie-chicken mortality risk. We hypothesized annual survival would be lower
135 for sites with less available grassland, individuals with less grassland in their home range, and
136 populations with a greater fragmented landcover configuration. We also expected to find
137 anthropogenic features that can act as perches or habitat for predators (power lines, fences, oil
138 wells) would increase the mortality risk for female lesser prairie-chickens.

139 METHODS

140 STUDY AREA

141 We selected study sites for areas known to have populations of lesser prairie-chickens.
142 Three study sites were located in three ecoregions across the range of lesser prairie-chickens in
143 Kansas (Fig. 1). Ecoregions were characterized by different landscape configuration, soil types,
144 plant assemblages, management regimes, and vegetation conditions (McDonald *et al.*, 2014;
145 Dahlgren *et al.*, 2016; Haukos *et al.*, 2016; Wolfe *et al.*, 2016).

146 Our study site in Northwestern Kansas, was in the Short-Grass Prairie/Conservation
147 Reserve Program (CRP) Mosaic Ecoregion (McDonald *et al.*, 2014). The Northwestern
148 population of lesser prairie-chickens may have recently expanded north of the Arkansas River
149 (Bain, 2002; Fields *et al.*, 2006; Oyler-McCance *et al.*, 2016; Rodgers, 2016). The Northwestern

150 study area (38°50'15.624''N, 100°46'8.546''W) was 1714 km² and located in Gove and Logan
151 counties. The primary land uses in this area were livestock grazing, energy extraction, CRP, and
152 both dryland and row-crop agriculture on silt-loam soils (Table 1).

153 In southern Kansas, lesser prairie-chickens are found in the Mixed-Grass Prairie
154 Ecoregion, with some areas exhibiting vegetation characteristics similar to the Sand Sagebrush
155 Prairie Ecoregion (McDonald *et al.*, 2014). We had two sites in south-central Kansas. The Red
156 Hills study site (37°21'17.102''N, 99°7'13.45''W) was 491 km², primarily on private lands in
157 Kiowa and Comanche counties within the Mixed-Grass Prairie Ecoregion. Primary land uses for
158 this area included livestock grazing, oil and gas extraction and exploration, and interspersed row-
159 crop agriculture. The Clark County study site (37°9'34.155''N, 99°52'45.61''W) within south-
160 central Kansas was 712 km² and located on the boundary of the Mixed-Grass Prairie and Sand
161 Sagebrush Prairie Ecoregions. Land use was dominated by livestock grazing, oil and gas
162 extraction, and row-crop agriculture (Table 1).

163 CAPTURE

164 We trapped lesser prairie-chickens at leks in spring (March–May) during 2013 and 2014
165 using walk-in drift traps and dropnets (Haukos *et al.*, 1990; Silvy *et al.*, 1990; Schroeder and
166 Braun, 1991). Lesser prairie-chickens were identified to sex using the presence of air-sacs,
167 greater pinnae length in males, and tail color patterns (Copelin, 1963).

168 We fitted female lesser prairie-chickens with either a 12- to 15-g bib-style very-high-
169 frequency (VHF) transmitter (A3960, Advanced Telemetry System, Isanti, MN, U.S.A.) or a
170 rump-mounted 22-g Satellite Platform Transmitting Terminal GPS transmitter (PTT-100,
171 Microwave Telemetry, Columbia, MD, U.S.A.). We attached SAT-PTT transmitters on the rump
172 using leg harnesses made of Teflon® ribbon with elastic at the front of the harness for flexibility

173 (Dzialak *et al.*, 2011). All capture and handling procedures were approved by the Kansas State
174 University Institutional Animal Care and Use Committee (protocol 3241). Field work was
175 conducted under Kansas Department of Wildlife, Parks and Tourism scientific collection permits
176 (SC-042-2013 and SC-079-2014).

177 TRACKING

178 We located female prairie-chickens outfitted with VHF transmitters via triangulation 3–4
179 times per weeks from March 2013–March 2015. Upon detection, individuals were triangulated
180 from three to five points to their estimate location. A three-element hand-held Yagi antenna and
181 receiver were used to take compass bearings on individuals. Bearings were ≥ 15 degrees apart
182 and taken within 20 min to decrease error from bird movement. Bearings and Universal
183 Transverse Mercator (UTM) positions were entered into the program Location of a Signal
184 (LOAS; Ecological Software Solutions LLC, Hegymagas, Hungary) to estimate the UTM
185 location of the bird and calculate an error polygon around the point. Error around VHF locations
186 ranged from zero to 1 ha. Fixed-wing aircraft were used to locate individuals with VHF radios
187 that had dispersed from the study site.

188 Birds outfitted with a Satellite-PTT transmitter had up to ten locations recorded per day
189 between 0600 and 2200 with 18 m accuracy. Points were uploaded to the Argos satellite system
190 every three days and downloaded weekly for mortality assessments.

191 SURVIVAL ANALYSIS

192 We delineated study site boundaries by creating Minimum Convex Polygons (MCP)
193 using the Minimum Bounding Geometry tool in ArcGIS 10.2 (ESRI Inc., 2013, Redlands, CA,
194 U.S.A.) around all recorded bird points for each field site for the first year of study. We also
195 buffered the study areas at two distances from the centroid of the study area to determine if our

196 study sites were representative of the surrounding landscape and if female survival at the study
197 sites reflected our delineated study sites or the surrounding landscape. We used a 25 km buffer to
198 standardize study site shape to a circle for a direct comparison among study sites, as 25 km was
199 the greatest distance from the centroid of any one study area to the outside of the study area
200 MCP; and a 50 km buffer to represent the overall landscape that lesser prairie-chickens may
201 encounter during dispersal (Earl *et al.*, 2016). Buffers were limited to the current estimated range
202 of the lesser prairie-chicken, as this was the extent of the landcover layer used.

203 For landscape metrics, we used a 2013 landcover layer of the lesser prairie-chicken range
204 developed by Spencer *et al.* (2017) from 30 m x 30 m resolution Landsat imagery. The landcover
205 layer included five landcover classes (patch types: grassland, crop, CRP, urban, and water) but
206 grassland and CRP did not distinguish grassland type or structure. Although the 50 km buffer
207 was limited to the extent of the lesser prairie-chicken range landcover layer, comparison with
208 aerial imagery confirmed that the landscape outside of the range was similar to that where the
209 presumed occupied range stops. We merged the landcover layer with the 2014 CRP layer from
210 the U.S. Department of Agriculture, Farm Services Agency, and clipped the landcover layer
211 using the Clip tool in ArcGIS 10.2 to the shape of each study site. We then used program
212 FRAGSTATS to describe landscape configuration within each study site (McGarigal *et al.*,
213 2012). The contagion metric, interspersion and juxtaposition index (IJI), mean patch size, and
214 standard error of mean patch size were calculated within each study site polygon, and for 25 km
215 and 50 km buffers around the centroid of the study site as measures of landscape configuration.
216 We used the contagion and IJI metrics as a way to describe the fragmentation within each study
217 site. Contagion is scaled 0 to 100, where a value of zero equates to a landscape in which there are
218 no like adjacencies and a value of 100 is a single patch type. Alternatively, the IJI uses the

219 proportion of like adjacencies on a cell-basis, with a high IJI representing an increasingly
220 fragmented landscape. We also calculated landscape composition of grassland, cropland, and
221 CRP as the percent occurrence of each within the landscape of each study site and 25 and 50 km
222 buffers around the centroid of each study site (Fig. 2).

223 To calculate individual covariates for the model testing the effect of landscape
224 characteristics on survival, we created MCPs for all individuals that had ≥ 3 unique points with
225 error polygons ≤ 1 ha around each point as an estimate of home range (Table 2). Each bird-year
226 (March 15th–March 14th) was treated as an independent period due to variation in weather and
227 land management across years (*e.g.*, precipitation, application of prescribed fire, haying, crop
228 types, and grazing density). Use of MCPs allow for determination of a single, contiguous
229 landscape potentially available for each individual, as kernel density estimates and Brownian
230 Bridge Movement Models generated for these birds from space-use analyses were composed of
231 disjointed polygons (Plumb, 2015; Robinson *et al.*, 2017). We used the same landcover data as
232 for the study site analysis, except clipped to the MCP of each bird. Landscape metrics were
233 calculated using FRAGSTATS to measure landscape composition and configuration within the
234 home range of each bird. Patches were truncated at the edge of the MCP, as we were unable to
235 determine a bird's perception of the landscape past where we had location information.
236 Landscape configuration metrics calculated within home ranges were total area, mean patch size,
237 contagion, IJI, and patch richness (McGarigal and Marks, 1995). Patch richness was the number
238 of different patch types within each home range. For landscape composition metrics, we
239 calculated the percentage of each home range that was grassland, cropland, or CRP. We tested
240 for correlation among the configuration metrics using Pearson's correlation coefficient; if a
241 metric pair was correlated at greater than $|r| = 0.5$, we did not include both in the same model.

242 We used FRAGSTATS metrics of configuration as individual covariates in one model set
243 and FRAGSTATS metrics of composition as individual covariates in a second model set to
244 derive functional relationships (White and Burnham, 1999). We created 14 *a priori* models using
245 individual FRAGSTATS configuration metrics, additive site and FRAGSTATS metrics, and
246 interactive site and FRAGSTATS metrics, followed by ranking of the models using AIC_c. We
247 also created 19 *a priori* models using composition metrics, including study site and quadratic
248 terms.

249 We used known-fate models in Program MARK to estimate cumulative annual survival
250 for female lesser prairie-chickens at each study site for two bird-years (March 15, 2013–March
251 14, 2014 and March 15, 2014–March 14, 2015; White and Burnham 1999). We tested five
252 models, including a null model, a site model, a year model, a site and year additive model and a
253 site and year interactive model. Models were ranked using Akaike’s Information Criterion
254 corrected for small sample size (AIC_c; Burnham and Anderson, 2002). Models with a $\Delta AIC_c \leq 2$
255 were considered competing models. We also modeled weekly survival using the known-fate
256 model in Program MARK to evaluate the effect of landscape characteristics on the survival of
257 individuals (White and Burnham, 1999; Winder *et al.*, 2014b). Encounter histories for both
258 models were compiled using weekly encounters across the 52 wk annual period, although sample
259 sizes varied due to the need for enough points to create MCPs.

260 ANDERSEN-GILL MODELING

261 We used an Andersen-Gill modeling framework to identify how continuous, encounter
262 specific covariates affects mortality risk for lesser prairie-chickens (Dinkins *et al.*, 2014; Winder
263 *et al.*, 2017). The mortality risk from Andersen-Gill models is the change in the survival rate
264 with each change in a given covariate (Johnson *et al.*, 2004a). Andersen-Gill models use Cox

265 proportional hazard models, but instead of having an entry date, exit date, and event for each
266 individual, this approach models entry, exit, and event for each encounter per individual
267 (Andersen and Gill, 1982). Use of Andersen-Gill models allows for time periods that individuals
268 were not present in the study, such as dispersal from the study site, transmitter malfunctions, or
269 lack of daily monitoring, such as with VHF individuals. The Andersen-Gill framework also
270 allows for left-censoring of individuals with staggered entry into the data set (Johnson *et al.*,
271 2004b).

272 We only used birds that had ≥ 2 locations, one of which being the mortality location, to
273 model the effect of distance to anthropogenic features on mortality risk. To obtain a covariate for
274 the encounters of each individual bird, we created separate distance rasters of each study site for
275 distance to road, fence, distribution power line, oil well and known leks using the Euclidean
276 Distance tool in ArcGIS 10.2, with 30 m x 30 m grid cells. Oil well and road layers were
277 obtained from the Kansas GIS and Data Support Center (<http://www.kansasgis.org/>). We hand-
278 delineated fences based on field inspection. Distribution power line layers were from the Kansas
279 Corporation Commission (<http://www.kcc.state.ks.us/>). Each cell of a distance raster layer has a
280 value that identifies the distance that cell is from the nearest structure. For each use-point bird
281 location, we extracted the distance from the starting point of an encounter to each structure using
282 the Extract Multi Values tool in ArcGIS, as well as the landcover type from the landcover and
283 CRP layer. We centered and scaled all input variables (Schielzeth, 2010).

284 For VHF birds, all available points were used for encounters, as birds were not located
285 more than once on any given day. We randomly selected one point per bird per day for satellite
286 birds as the SAT-PTT birds had as many as 10 points available/day. We chose a point for each
287 day using the `r.sample` command in Geospatial Modeling Environment to simplify to a daily

288 encounter history and make use of both the SAT-PTT and VHF transmitter points (Beyer, 2015).
289 Only points and mortalities within the delineated study sites were used.

290 Using the ‘coxph’ function in the ‘survival’ package, we identified the relative effect of
291 covariates on mortality risk and annual survival from regression coefficients (Therneau, 2014).
292 We built 26 *a priori* models, which represented each variable alone, additive models of site and
293 variable combinations, and additive models of each combination of two variables. Model
294 diagnostics were tested with the ‘cox.zph’ function to determine if these data met assumptions of
295 proportional hazards (Fox and Weisberg, 2011). All models with $\Delta AIC_c \leq 2$ were considered
296 competing models. If the mortality risk from the top models differed from zero (*i.e.*, 95%
297 confidence intervals of the beta estimate did not overlap zero), then we judged the variable to be
298 biologically important and plotted the predicted risk curve.

299 RESULTS

300 STUDY SITE COMPOSITION AND CONFIGURATION

301 A total of 170 individuals, representing 193 bird years and 108 mortality events were
302 included in the overall model for annual known-fate survival of female lesser prairie-chickens,
303 81 individuals in 2013–2014 and 112 in 2014–2015. There were two top models in the model set
304 with $\Delta AIC_c \leq 2$, one representing differences among study sites ($w_i = 0.59$) and another
305 representing differences among study sites and years ($w_i = 0.22$, Table 3). We made inference
306 based on the top-ranked model representing differences among sites, as adding year did not
307 improve the model fit and was considered spurious. Northwest Kansas had a lower annual
308 survival estimate than any of the other sites, at 0.27 ($n = 110$, 95% CI = 0.20–0.38). Survival in
309 Northwestern Kansas was 50% lower than in Clark County, ($\hat{S} = 0.56$, $n = 25$, 95% CI = 0.38–
310 0.81). The annual survival of lesser prairie-chickens within the Red Hills was similar to the Clark

311 County site ($\hat{S} = 0.48$, $n = 58$, 95% CI = 0.36–0.64). The overall annual survival of female lesser
312 prairie-chickens across all study sites was 0.37 (95% CI = 0.30–0.45).

313 Sites differed in landscape configuration and composition metrics (Table 1). Calculated
314 FRAGSTATS contagion metrics within the study sites indicated Northwest Kansas was
315 fragmented relative to the Clark County and Red Hills sites (Table 1). Fragmentation was
316 evident, as contagion values were lower and IJI values were greater for the Northwest site
317 relative to the other study sites. Although high variation among patches resulted in no statistical
318 difference, point estimates of mean patch size were 34 and 47.6% smaller for the Northwestern
319 site relative to the Clark County and Red Hills sites, respectively. All study sites were less
320 fragmented than their corresponding 25 and 50 km buffered areas, with larger mean patch sizes
321 and larger contagion values (Table 1).

322 The Northwest site was composed of less grassland and more cropland than the other
323 study sites (Table 1). It has been hypothesized CRP compensates for the loss of native grassland
324 in the northern portion of the lesser prairie-chicken range, but including CRP as grassland still
325 resulted in the Northwest site supporting 15.2 and 25.3% less grassland than Clark County or the
326 Red Hills. Additionally, all study sites had more grassland and less cropland in the delineated
327 study areas than the 25 km or 50 km buffers (Table 1).

328 HOME RANGE COMPOSITION AND CONFIGURATION

329 We used 170 total bird-years to estimate relationships among weekly survival of lesser
330 prairie-chickens and home-range scale habitat configuration and composition. Home range size
331 was not correlated with the total number of points used to calculate the MCP ($r = 0.27$) and
332 neither home range size nor the number of points used to calculate the MCPs were correlated
333 with configuration metrics within home ranges. The average annual MCP home range size was

334 3749.43 ha (SE = 780.02). The IJI was negatively correlated with patch richness within home
335 ranges ($r = -0.52$); therefore, we only included patch richness as an individual covariate in
336 survival models, as contagion could still be used to assess patch isolation. The sample of
337 individuals for which survival was calculated included 96 mortality events. Only two models had
338 a $w_i > 0$, Site \times Patch Richness ($w_i = 0.85$, $AIC_c = 917.54$) and Site + Patch Richness ($w_i = 0.15$,
339 $AIC_c = 920.96$). The configuration metric model supported by the data was Site \times Patch
340 Richness, as Site + Patch Richness had a $\Delta AIC_c > 2$. For all sites there was a significant trend of
341 increasing survival as patch richness within home ranges increased ($\beta = 1.17$, 95% CI = 0.64–
342 1.69; Fig. 3).

343 The composition metrics (% crop, % grassland, and % CRP) were all correlated, and
344 therefore were not combined in models. There were two top-ranked models in the home-range
345 composition model set (Table 4). Top-ranked models were Site + % Crop² and Site + %
346 Grassland² models. Slope estimates for both models were significant for the linear terms ($\beta_{\text{crop}} =$
347 0.079 , 95% CI = 0.034–0.13 and $\beta_{\text{grass}} = 0.085$, 95% CI = 0.041–0.13, respectively) and the
348 quadratic terms ($\beta_{\text{crop}^2} = -0.0013$, 95% CI = -0.002–0.00025 and $\beta_{\text{grass}^2} = -0.00074$, 95% CI = -
349 0.0011 –0.00039, respectively) indicated a peak in weekly survival when proportion of crop
350 within a lesser prairie-chicken's home range was 31.3% and proportion of grassland within a
351 lesser prairie-chicken's home range was 57% (Fig. 4).

352 ANDERSEN-GILL

353 Using one encounter per day for each bird resulted in 18,063 encounters from 189 total
354 bird years with 96 total mortality events. The model best supported by these data was Site +
355 Distance to fence (Table 5). Across all Kansas study sites, mortality risk for female lesser
356 prairie-chickens increased as distance to fence decreased (Fig. 5). Regression coefficients in our

357 model indicate a greater magnitude of risk relative to decreased distance from fences for birds in
358 Northwest Kansas (mortality risk = 1.15, SE = 0.38) compared to Red Hills and Clark County
359 (Fig. 5).

360 DISCUSSION

361 We investigated effects of landscape composition and configuration on annual survival of female
362 lesser prairie-chickens in Kansas. We were able to identify habitat composition (crop = 31%,
363 grassland = 57%) amounts within home ranges to maximize weekly survival and determined that
364 home ranges with greater patch richness had a positive effect on survival. Annual survival varied
365 distinctly among our study sites, and we note the three sites also differed markedly in their
366 landscape composition, suggesting that landscape composition influences survival. Increased
367 survival for sites with more grassland cover indicates that a minimum threshold grassland area is
368 needed to support a lesser prairie-chicken population, between the levels seen in Northwest,
369 Kansas and Clark County (grassland composition 54 to 76%, respectively). Finally, we found
370 that mortality risk for lesser prairie-chickens were greatest in Northwest Kansas and increased as
371 distance to fences decreased for all sites.

372 Results from the individual-level (*i.e.*, home range) analysis were inconclusive in
373 showing that configuration of home ranges have an effect on survival rates. It is possible that
374 lesser prairie-chickens are already selecting areas for their home range within the range of
375 tolerable fragmentation, which we would be unable to detect with survival models, suggesting
376 lesser prairie-chickens perceive landscape factors outside of their home range. Alternatively, we
377 found that proportion of cropland (30%) and grassland (50–70%) within home ranges maximizes
378 weekly survival. These results add a survival-based mechanism to past studies that identified
379 occupied lesser prairie-chicken habitat occurred below a threshold of 37% cultivation and a more

380 recent study indicating that abundance and resiliency of lesser prairie-chickens decreased after
381 reaching a threshold of 9.6% cropland (Crawford and Bolen, 1976; Ross *et al.*, 2016a).

382 We also found a positive significant relationship with an increase in survival
383 corresponding with an increase in patch richness within home ranges. Increasing survival relative
384 to the number of patch types does not necessarily mean increased fragmentation increases
385 survival, as contagion metrics did not explain survival. The patch types themselves could exist in
386 small patches within the grassland matrix, providing additional cover and forage types; therefore,
387 not significantly increasing the breakup of grassland (Campbell, 1972). Instead, this may indicate
388 lesser prairie-chickens experience increased survival when they have a variety of available
389 landcover options within their home range. This relationship is intuitive, as spatial heterogeneity
390 benefits lesser prairie-chickens and other grassland birds, because they require different
391 landscape types throughout different life stages (Fuhlendorf and Engle, 2001; Sandercock *et al.*,
392 2014). Selection for heterogeneity also extends to finer scales, as lesser prairie-chickens select
393 for larger livestock pastures that exhibit greater structural heterogeneity (Kraft, 2016). Effects of
394 habitat loss have been shown to be greater than effects of fragmentation for species abundance,
395 species persistence, and reproduction (Andrén, 1994; Fahrig, 2003). A single female lesser
396 prairie-chicken can require thousands of hectares of space during her annual cycle, most of
397 which should be grasslands (Robinson *et al.*, 2017). Therefore, our data suggests lesser prairie-
398 chickens may exhibit enough mobility to navigate among the various patches to find the requisite
399 types of grassland for distinct life stages (*i.e.*, nesting, brooding, foraging, Hagen *et al.*, 2009).

400 Our survival estimates in Northwest Kansas were lower than any other published
401 estimates of annual lesser prairie-chicken survival, which range from 0.31 to 0.59, although
402 estimates from Red Hills and Clark County sites fall within the published range (Jamison, 2000;

403 Hagen *et al.*, 2007; Lyons *et al.*, 2009; Haukos and Zavaleta, 2016). Differences among the study
404 sites, with the Northwest site being more fragmented at the patch and cell level and also
405 comprised of less grassland, were evident at the study-site scale and within 25 km and 50 km
406 buffered landscapes. While differences among sites in proportion of landcover type may not
407 necessarily mean habitat loss in all landscapes, the Southern Great Plains region was nearly all
408 grass or shrub-dominated prairie before the arrival of European settlers and onset of agriculture
409 (Samson and Knopf, 1994). One of our most pronounced findings was that all of the study sites,
410 which were chosen due to their recognized densities of lesser prairie-chickens, were less
411 fragmented and comprised of more grassland than the surrounding landscape out to a 50 km
412 buffer. This suggests aggressive restoration efforts may be necessary to restore grassland at
413 broader scales and reduce fragmentation to increase the probability of lesser prairie-chicken
414 survival within their occupied range.

415 The effect of distance to anthropogenic features on annual survival indicated the closer an
416 individual was to a fence, the greater risk of mortality, and the risk varied regionally. Fence
417 collision risk has been shown to be significant in Oklahoma (Wolfe *et al.*, 2007). However,
418 increased mortality risk relative to fences in our study was unlikely to be attributed to collision
419 mortality as in a concurrent study Robinson *et al.* (2016) reported evidence for only 1
420 collision/187 km of fence surveyed despite walking >2800 km of fences and documenting 1
421 mortality for 12,706 documented fence crossings by transmittered lesser prairie-chickens. Instead
422 of collision risk, the increased mortality risk in relation to fences in Kansas could be due to a
423 relationship with increasing predator densities at patch edges. Fences are frequently used as
424 perches by raptors, one of the most common lesser prairie-chicken predators (Hagen *et al.*, 2007;
425 Behney *et al.*, 2012; Boal, 2016). Fences also serve as corridors for mammalian predators, such

426 as coyotes (*Canis latrans*) or red fox (*Vulpes vulpes*), that are known predators of grassland
427 birds. Increase of predation risk is especially relevant in working grasslands where two-track
428 roads tend to coincide with fences, which can act as mammalian movement corridors (Bradley
429 and Fagre, 1988). Our analysis indicated distance to powerline, oil well, or road had little
430 influence on lesser prairie-chicken mortality risk, contrary to Hovick *et al.* (2014) reporting these
431 anthropogenic features negatively affected survival and lek persistence for other grouse species.
432 Lesser and greater prairie-chickens (*Tympanuchus cupido*) have already been shown to exhibit
433 avoidance behavior of anthropogenic features such as power lines (Hagen *et al.*, 2011), and wind
434 turbines (Winder *et al.*, 2014a), so if avoidance has already occurred, detection of an effect on
435 survival may be difficult.

436 Combining evidence from all three sets of survival estimation, lesser prairie-chickens in
437 Northwestern Kansas are likely to experience lower survival in the long-term relative to the other
438 study sites in Kansas, due to greater mortality risk. The percentage of grassland in Northwest
439 Kansas (54%) may be near the threshold for persistence of lesser prairie-chickens. Prior to the
440 establishment of the CRP in Kansas, lesser prairie-chickens were not detected in Northwestern
441 Kansas (Rodgers, 2016). Properties enrolled in the CRP generally replaced cropland, as prior to
442 CRP many landscapes exceeded the cropland threshold for persistence of lesser prairie-chickens.
443 Grasses in CRP grasslands also contribute structural heterogeneity to the short-grass prairie
444 landscape (Kraft, 2016; Spencer *et al.*, 2017). Without continued support and enrollment of land
445 into CRP, the landscape currently supporting lesser prairie-chickens in Northwestern Kansas
446 could easily dip below the threshold level of grassland and negatively affect annual survival and
447 population growth rates.

448 Although we were able to identify a home range landcover composition that increased
449 annual survival, the optimum cropland composition was exceeded within the Northwest study
450 site and 25 km and 50 km buffers. Therefore, it is less likely for birds to have the ability to place
451 their home ranges in areas to reach this optimum composition in the Northwest population,
452 which could have contributed to the relatively low annual survival. Furthermore, our conclusions
453 are based on a landcover layer that does not distinguish grassland structure appropriate for lesser
454 prairie-chickens (*i.e.*, mixed-grass prairie compared to short-grass prairie: Spencer *et al.*, 2017).
455 We may have overestimated the amount of grassland available for lesser prairie-chickens in the
456 western, more arid, portion of the species range by including short-grass prairie, where grassland
457 management can leave grassland unsuitable for lesser prairie-chickens (Hagen *et al.*, 2004).
458 Consideration of available grassland structure and reduced grassland area at buffers surrounding
459 our study areas could lead to less available habitat within these ecoregions than we presumed,
460 such that if birds disperse from the immediate study area, they would have little chance of
461 finding available habitat resulting in an increased likelihood of succumbing to mortality (Earl *et*
462 *al.*, 2016, D. Haukos, unpubl. Data).

463 Our study was partially conducted during and following a period of severe drought (2012
464 and 2013), which has been linked to lesser prairie-chicken declines (Ross *et al.*, 2016b). The
465 drought could have depressed survival rates if structure of residual vegetation was insufficient to
466 provide concealment from predators (Ross *et al.*, 2016b). Across all sites and years, the majority
467 of mortality events occurred during the nesting season, before the growing season for warm-
468 season grasses (Plumb, 2015; Robinson, 2015). The lack of residual vegetation during drought
469 could have left female lesser prairie-chickens at all sites more exposed on their nests (Hagen and
470 Giesen, 2005; Grisham *et al.*, 2016a), but the northwest portion of the lesser prairie-chicken

471 range in Kansas is more arid than the south-central sites, so the effect of drought could have
472 exacerbated mortality and further explain lower survival in this region during our study
473 (Robinson *et al.*, 2017). Additionally, the increase of survival with an increasing number of patch
474 types could link to drought, as lesser prairie-chickens may seek out CRP for the increased cover
475 (Spencer *et al.*, 2017) and cropland for foraging opportunities (Campbell, 1972).

476 Given our results, managers interested in benefiting lesser prairie-chicken populations
477 and increasing their resiliency to intensive drought could maintain grassland within the core
478 occupied lesser prairie-chicken range and restore croplands adjacent to grasslands. Spatial
479 heterogeneity of conserved grassland would increase occupancy and available habitat for
480 required life stages (Hagen *et al.*, 2009, 2016). Additionally, to increase occupied range of the
481 lesser prairie-chicken, the amount of grassland in landscapes outside of the areas where lesser
482 prairie-chickens currently persist needs to be increased to surpass the 50–70% threshold, within
483 an average lesser prairie-chicken home range, to improve survival. Dispersal may be facilitated
484 by restoring grassland close to existing lesser prairie-chicken populations to increase the
485 probability of range expansion (Earl *et al.*, 2016). If grasslands are reduced below the threshold
486 of landscape composition required for lesser prairie-chickens, we could see declines in adult
487 female survivorship. Increased CRP enrollment may supplement native grassland, especially
488 within the short-grass prairie (Hagen *et al.*, 2016), and targeted enrollment should occur close to
489 existing lesser prairie-chicken populations and in close proximity to grassland to increase the
490 likelihood of population persistence. Future research would benefit by investigating landscape
491 connectivity and the ability of birds to disperse through different landscape configurations to
492 prioritize areas for grassland conservation and management.

715

716

717 TABLE 2.— Total available lesser prairie-chicken locations from three Kansas study sites collected
 718 using satellite transmitters (SAT-PTT) and very-high-frequency (VHF) transmitters used to
 719 calculate minimum convex polygons during 2013–2015. Reported means are the mean of
 720 number of points per bird used to calculate the MCP.

721

Site	SAT-PTT			VHF		
	Number of Birds	Total Number of Points	Mean Points Per Bird (SE)	Number of Birds	Total Number of Points	Mean Points Per Bird (SE)
Clark County	17	30,497	1,793 (246)	7	503	71 (20)
Northwest	58	78,379	1,351 (149)	36	1,251	34 (5)
Red Hills	31	37,740	1,217 (165)	21	1,228	58 (10)

722

723

724 TABLE 3.—Comparison of models in Program MARK used to explain variation in annual survival
 725 of female lesser prairie-chickens in Kansas for 2013–2014 and 2014–2015. Data from three sites
 726 were included in these models; Clark County, Red Hills, and Northwest
 727

Model	K*	Deviance	ΔAIC_c	w_i^*
Site	3	1029.09	0.00	0.59
Site + Year	4	1029.08	2.00	0.22
Site * Year	6	1027.70	2.62	0.16
Constant	1	96.89	6.12	0.03
Year	2	1036.59	7.50	0.01

*K = Number of parameters, w_i = Model weight,

AICc of top-ranked model = 1033.09

728

729

730 TABLE 4.—Comparison of models in Program MARK used to explain variation in landscape
 731 composition on survival of female lesser prairie-chickens in Kansas during 2013–2014 and
 732 2014–2015. Model ranking based on Akaike Information Criterion corrected for small sample
 733 size (AIC_c) for 19 models, including a null model. Site models considered three study sites –
 734 Northwest, Kansas, Red Hills, and Clark County, Kansas. Models with no support ($w_i = 0$) were
 735 not included in these results

Model	K*	Deviance	ΔAIC_c	w_i^*
Site + %Crop ²	5	920.64	0	0.36
Site + %Grass ²	5	920.80	0.15	0.33
Site * %Crop ²	9	915.56	2.95	0.08
Site * %Grass ²	9	917.61	2.99	0.08
Site * %Crop	6	921.76	3.12	0.08
Site + %Crop	4	925.96	3.32	0.07

*K = Number of parameters, w_i = Akaike model weight, $AIC_c =$

960.36 for the best fit model

737 TABLE 5.—Model ranking for Andersen-Gill models, based on Akaike Information Criterion
 738 corrected for small sample size (AIC_c) for 26 models, including a null model, determining the
 739 effect of distance to anthropogenic features and landcover type (grassland, cropland, and CRP)
 740 on survival of lesser prairie-chickens in Kansas during 2013–2015. Models with no support ($w_i =$
 741 0) were not included in these results.

Model	K*	Deviance	Δ AIC _c	w_i^*
Site + Fence	3	784.44	0	0.71
Site * Fence	5	782.52	2.07	0.25
Site + Lek	3	792.44	7.99	0.01
Site + Oil	3	794.16	9.72	0.01

*K = Number of parameters; AIC_c = 790.45 for the best fit

model; w_i = Akaike model weight

742

743

744

745 FIG. 1.—Study sites in Kansas used to test the effect of landscape fragmentation on survival of
746 female lesser prairie-chickens during 2013–2015. The underlying gray region represents the
747 current estimated lesser prairie-chicken range within Kansas. Polygons indicate our Northwest
748 Kansas study sites in Gove and Logan counties, our Red Hills study site in Kiowa and Comanche
749 counties, and our Clark site in Clark County, Kansas

750

751 FIG. 2.—Landscape composition of study sites from Northwestern Kansas (Gove and Logan
752 counties; top), Clark (Clark County, Kansas; center), and Red Hills (Kiowa and Comanche
753 counties; bottom), illustrating that study sites have different proportions of landcover types,
754 which differed from the surrounding landscape and represented as a 50 km buffer from the
755 centroid of the study site

756

757 FIG. 3—Functional relationships from Program MARK for weekly survival of lesser prairie-
758 chickens versus patch richness within individual home ranges in Kansas during 2013–2015.
759 Patch richness is the number of patch types that occurred in each individual home range

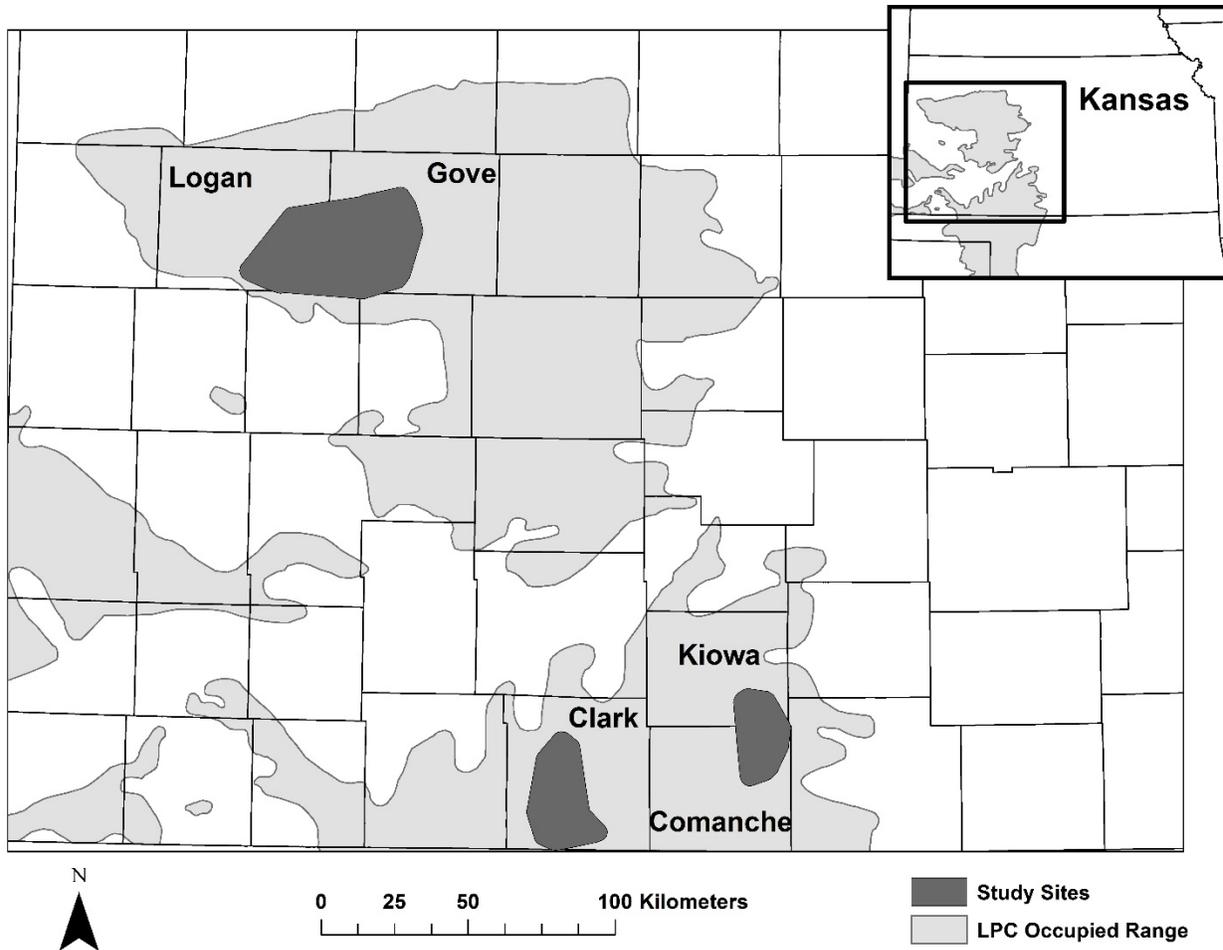

760

761 FIG. 4—Functional relationships from Program MARK for weekly survival of lesser prairie-
762 chickens versus percent crop (**A**) and percent grassland (**B**) within individual home ranges during
763 2013–2015 for three sites in Kansas

764

765 FIG. 5—Predicted mortality risk of female lesser prairie-chickens for distance to fence from
766 Andersen-Gill models for continuous encounter covariates during 2013–2015. Site + distance to
767 fence (m) predicted curve, with three different study sites in Kansas (Clark County, Red Hills,

768 and Northwest). Predicted curves only represent mortality risk for distance to fence that we
769 located mortalities. Mortality risk from this model indicate that lesser prairie-chickens in
770 Northwest Kansas experience greater risk (mortality risk at distance 0 = 2.49, 95% CI = 1.88–
771 3.09) in relation to fences than lesser prairie-chicken in the Red Hills (mortality risk at distance 0
772 = 1.32, 95% CI = 0.78–1.86) and Clark County (mortality risk at distance 0 = 0.79, 95% CI =
773 0.20–1.37) study sites
